How to go to your page:

This eBook contains four volumes. Each volume of the original hardcopy set is numbered separately. In order to avoid duplicate pagination in this eBook, we have included volume numbers within the page numbers.

For example, to go to page 5 of the first volume, enter I-5 in the “page #” box at the top of the screen and click “Go”. To go to page 100 of the second volume enter II-100. To go to page xiv of the third volume enter III-xiv, and so on.

Sustainable Agriculture and Food

Library of Congress Cataloging-in-Publication Data has been applied for

The paper used for this book is FSC-certified and elemental chlorine-free. FSC (the Forest Stewardship Council) is an international network to promote responsible management of the world's forests.

Contents

VOLUME I HISTORY OF AGRICULTURE AND FOOD

Part III Agricultural Revolutions and Change

Part IV Modern Agricultural Reforms

VOLUME II AGRICULTURE AND THE ENVIRONMENT

Part III Communities and Social Capital

Part IV Ecological Restoration and Design

VOLUME III AGRICULTURE AND FOOD SYSTEMS

Part I The Global Food System

Part II Poverty and Hunger

Part III Diet and Health

Part IV Localized Food Systems

VOLUME IV POLICIES, PROCESSES AND INSTITUTIONS

Part I Ethics and Systems Thinking

Part II Participatory Processes

Part III Governance and Education

List of Acronyms and Abbreviations

AARD	Agency for Agricultural Research and Development
AFTPs	Agroforestry Tree Products
ARPAC	Agricultural Reseach Policy Advisory Committee
BTZ	Biotechnology Trust of Zimbabwe
CAAS	Chinese Academy of Agricultural Sciences
CAS	Chinese Academy of Sciences
CBD	Convention on Biological Diversity
CENFOR	Center for Forestry Research (Amazon)
CGIAR	Consultative Group on International Agricultural Research
CHAGS	Conference on Hunting and Gathering Societies
CIAT	Centro Internacional de Agricultura Tropical
CIMMYT	Centro Internacional de Mejoramento de Maíz y Trigo
CIP	Centro Internacional de Papas
CODESU	Consorcio para el Desarrollo Sostenible de Ucayali
CPR	common property regime
CRIFC	Central Research Institute for Food and Crops
CSP	Conservation Security Program
EA	Environment Agency (UK)
EDRSS	Ecological Demonstrative Rebuilding for Sustainable Settlements
ESSO	Standard Oil of New Jersey
FAO	Food and Agriculture Organization (UN)
GDP	gross domestic product
GIS	geographic information system
IBP	International Biological Program
IBPGR	International Board for Plant Genetic Resources
ICA	Instituto Columbiano Agropecuário
ICRAF	International Centre for Research in Agroforestry
ICRISAT	International Crops Research Institute for the Semi-Arid Tropics
IFAD	International Fund for Agricultural Development
IFS	integrated farming system
IIAP	Instituto de Investigación de la Amazonía Peruana
IITA	International Institute of Tropical Agriculture
INAC	Indian and Northern Affairs Canada
INIA	Instituto Nacional de Investigación Agraria
INIFAP	Instituto Nacional de Investigaciones Forestales, Agricolas y Pecuarias

INRM	integrated natural resource management
IPCC	Intergovernmental Panel on Climate Change
IPM	integrated pest management
IRAD	Institut de Recherche Agricole pour le Développement
IRRI	International Rice Research Institute
IUCN	International Union for the Conservation of Nature and Natural Resources
LMO	living modified organism
MEA	Millennium Ecosystem Assessment
NBC	national biosafety committee
NBF	national biosafety framework
NEP	New Economic Policy (Russia)
NGO	non-governmental organization
PCARRD	Philippine Council for Agriculture, Forestry, and Natural Resources Research
PFI	Practical Farmers of Iowa
PFTs	plant functional types
RDAs	recommended daily allowances
SADC	Southern African Development Community
SARD	Sustainable Agriculture and Rural Development
SRI	system of rice intensification
TAC	Technical Advisory Committee

WCED	World Commission on Environment and Development
WN	World Neighbors
WTO	World Trade Organization

Overview to Four Volumes: Sustainable Agriculture and Food

Jules Pretty

The Context for Agricultural Sustainability

The interest in the sustainability of agricultural and food systems can be traced to environmental concerns that began to appear in the 1950s and 1960s. However, ideas about sustainability date back at least to the oldest surviving writings from China, Greece and Rome (King, 1911; Cato, 1979; Hesiod, 1988; Conway, 1997; Li Wenhua, 2001; Pretty, 2002). More recent concerns began to develop during the 1960s, and were particularly driven by Rachel Carson's book *Silent Spring* (Carson, 1963). Like other popular and scientific studies at the time, it focused on the environmental harm caused by agriculture. In the 1970s, the Club of Rome identified the economic problems that societies would face when environmental resources were overused, depleted or harmed, and pointed towards the need for different types of policies to generate sustainable economic growth.

In the late 1980s, the World Commission on Environment and Development (WCED), chaired by Gro Harlem Brundtland, published *Our Common Future*, the first serious attempt to link poverty alleviation to natural resource management and the state of the environment. Sustainable development was defined as 'meeting the needs of the present without compromising the ability of future generations to meet their own needs'. The concept implied both limits to growth and the idea of different patterns of growth (WCED, 1987).

In 1992, the UN Conference on Environment and Development was held in Rio de Janeiro. The main outcome was Agenda 21, a 41-chapter document setting out priorities and practices across all economic and social sectors, and how these should relate to the environment. Chapter 14 addressed Sustainable Agriculture and Rural Development (SARD). The principles of sustainable forms of agriculture that encouraged minimizing harm to the environment and human health were agreed. However, progress since then has not been good, as Agenda 21 was not a binding treaty on national governments, and all remain free to choose whether to adopt or ignore these principles (Pretty and Koohafkan, 2002). The

'Rio Summit' was, however, followed by several important actions that came to affect agriculture, including the signing of the Convention on Biodiversity in 1995; the establishment of the UN Global Integrated Pest Management (IPM) Facility in 1995, which provides international guidance and technical assistance for integrated pest management; the signing of the Stockholm Convention on Persistent Organic Pollutants in 2001, so addressing some problematic pesticides; and, ten years after Rio, the World Summit on Sustainable Development held in Johannesburg. In 2005, the Millennium Ecosystem Assessment then drew attention to the value of environmental services, and in particular the role that agriculture plays in affecting them (MEA, 2005).

Today, concerns about sustainability centre on the need to incorporate agricultural technologies and practices that (i) do not have adverse effects on the environment (partly because the environment is an important asset for farming); and (ii) are accessible to and effective for farmers, and lead both to improvements in food productivity and have positive side-effects on environmental goods and services. Sustainability in agricultural systems incorporates concepts of both resilience (the capacity of systems to buffer shocks and stresses) and persistence (the capacity of systems to continue over long periods), and addresses many wider ecological, economic and social and political dimensions:

- *Ecological* – the core concerns are to reduce negative environmental and health externalities, to enhance and use local ecosystem resources, and preserve biodiversity. More recent concerns include broader recognition of the positive environmental services from agriculture (including carbon capture in soils, flood protection, biodiversity services).
- *Economic* – economic perspectives seek to assign value to ecological assets, and also to include a longer time frame in economic analysis. They also highlight the often hidden subsidies that promote the depletion of resources or unfair competition with other production systems.
- *Social and political* – there are many concerns about the equity of technological change. At the local level, agricultural sustainability is associated with farmer participation, group action and the promotion of local institutions, culture and farming communities. At the higher level, the concern is for enabling policies that target poverty reduction in developing countries and diet management in industrialized countries.

In recent decades, there has been remarkable growth in agricultural production worldwide. Since the beginning of the 1960s, aggregate world food production grew by 145 per cent to the early part of the 21st century. In Africa, it increased by 140 per cent, in Latin America by almost 200 per cent and in Asia by 280 per cent. The greatest increases have been in China, where a five-fold increase occurred, mostly during the 1980s and 1990s. In industrialized countries, production started from a higher base; yet it still doubled in the US over 40 years, and grew by 68 per cent in western Europe (FAO, 2005).

Over the same period, world population grew from 3 to 6.5 billion. Again, though, per capita agricultural production has outpaced population growth. For each person today, there is 25 per cent more food compared with 1960. These aggregate figures, however, hide important regional differences. In Asia and Latin America, per capita food production increased by 76 per cent and 28 per cent respectively. Africa has fared badly, with food production per person 10 per cent lower in the early 2000s than in 1960. China, again, performed best, with a trebling of per capita food production over the same period. These agricultural production gains have lifted millions out of poverty and provided a platform for both rural and urban economic growth in many parts of the world.

However, these advances in aggregate productivity have not brought reductions in the incidence of hunger for all. In the early 21st century, there were still more than 800 million people hungry and lacking adequate access to food. A third were in East and South-East Asia, another third in South Asia, a quarter in sub-Saharan Africa, and 5 per cent each in Latin America/Caribbean and in North Africa/Near East. Nonetheless, there has been progress, as the incidence of undernourishment stood at 960 million in 1970, comprising a third of all people in developing countries at the time.

Despite this progress in food output, it is likely that food-related ill health will remain widespread for many people. As world population continues to increase, until at least the mid 21st century, so the absolute demand for food will also increase. Increasing incomes will also mean people will have more purchasing power, and this will increase demand for food. But as diets change, so demand for the types of food will also shift radically, with large numbers of people going through the nutrition transition. In particular, increasing urbanization means people are more likely to adopt new diets, particularly consuming more meat, fats and refined cereals, and fewer traditional cereals, vegetables and fruit (Popkin, 1998).

At the same time as these recent changes in agricultural productivity, consumer behaviour over food and the political economy of farming and food (Goodman and Watts, 1997), agricultural systems are now recognized to be a significant source of environmental harm (Tilman, 1999; Pretty et al, 2000; MEA, 2005; Pretty, 2007). Since the early 1960s, the total agricultural area has expanded by 11 per cent from 4.5 to 5 billion hectares, and arable area from 1.27 to 1.4 billion hectares. In industrialized countries, agricultural area has fallen by 3 per cent, but has risen by 21 per cent in developing countries (Figure 1a). Livestock production has also increased, with a worldwide four-fold increase in numbers of chickens, a two-fold increase in pigs, and 40–50 per cent increases in numbers of cattle, sheep and goats (Figure 1b).

During this period, the intensity of production on agricultural lands has also risen substantially. The area under irrigation and number of agricultural machines has grown by about two-fold, and the consumption of all fertilizers by four-fold (and nitrogen fertilizers by seven-fold) (Figures 1c and 1d). The use of pesticides in agriculture has also increased dramatically, and now amounts to some 2.56

billion kilogrammes (kg) per year. In the early 21st century, the annual value of the global market was US$25 billion, of which some $3 billion of sales was in developing countries (Pretty, 2005). Herbicides account for 49 per cent of use, insecticides 25 per cent, fungicides 22 per cent, and others about 3 per cent (Table 1). A third of the world market by value is in the US, which represents 22 per cent of active ingredient use. In the US, though, large amounts of pesticide are used in the home/garden (17 per cent by value) and in industrial, commercial and government settings (13 per cent by value).

These factors of production have had a direct impact on world food production (Figures 2a–c). There are clear and significant relationships between fertilizer consumption, number of agricultural machines, irrigated area, agricultural land area and arable area with total world food production (comprising all cereals, coarse grains, pulses, roots and tubers, and oil crops). The inefficient use of some of these inputs has, however, led to considerable environmental harm. Increased agricultural area contributes substantially to the loss of habitats, associated biodiversity and their valuable environmental services (MEA, 2005). Some 30–80 per cent of nitrogen applied to farmland escapes to contaminate water systems and the atmosphere, as well as increasing the incidence of some disease vectors (Victor and Reuben, 2002; Smil, 2001; Pretty et al, 2003a; Townsend et al, 2003; Giles, 2005). Irrigation water is often used inefficiently, and causes waterlogging and salinization, as well as diverting water from other domestic and industrial users, and agricultural machinery has increased the consumption of fossil fuels in food production (Leach, 1976; Stout, 1998).

These relationships clearly show the past effectiveness of these factors of production in increasing agricultural productivity. One argument is to suggest that the persistent world food crisis indicates a need for substantially greater use of these inputs (Avery, 1995; Trewevas, 2001; Cassman et al, 2002; Green et al, 2005; Tripp, 2006). But it would be both simplistic and optimistic to assume that

Figure 2c *Relationship between world agricultural land area and world plant food production (1961–2002)*

all these relationships will remain linear in the future, and that gains will continue at the previous rates (Tilman, 1999). This would assume a continuing supply of these factors and inputs, and that the environmental costs of their use will be small. There is also growing evidence to suggest that this approach to agricultural growth has reached critical environmental limits, and that the aggregate costs in terms of lost or forgone benefits from environmental services are too great for the world to bear (Ruttan, 1999; MEA, 2005). The costs of these environmental problems are often called externalities, as they do not appear in any formal accounting systems. Yet many agricultural systems themselves are now suffering because key natural assets that they require to be plentiful are being undermined or diminished.

Agricultural systems in all parts of the world will have to make many improvements. In some, the challenge is to increase food production to solve immediate problems of hunger. In others, the focus will be more on adjustments that maintain food production whilst increasing the flow of environmental goods and services. World population is set to continue to increase until about 2040–2050, and then is likely to stabilize or fall because of changes in fertility patterns. The high fertility projection by the UN (2005) is unlikely to arise, as shifts towards lower fertility have already occurred in many countries worldwide, and so there are very real prospects of world population eventually falling over the one to two centuries after the maximum is reached. This suggests that the agricultural and food challenge is likely to be most acute in the next 50–100 years, and thereafter qualitatively change according to people's aggregate consumption patterns.

What is Sustainable Agriculture?

What, then, do we now understand by agricultural sustainability? Many different expressions have come to be used to imply greater sustainability in some agricultural systems over prevailing ones (both pre-industrial and industrialized). These include the terms biodynamic, community-based, ecoagriculture, ecological, environmentally-sensitive, extensive, farm-fresh, free-range, low-input, organic, permaculture, sustainable and wise-use (Pretty, 1995; Conway, 1997; NRC, 2000; McNeely and Scherr, 2003; Clements and Shrestha, 2004; Cox et al, 2004; Gliessman, 2005). There is continuing and intense debate about whether agricultural systems using some of these terms can qualify as sustainable (Balfour, 1943; Lampkin and Padel, 1994; Altieri, 1995; Trewevas, 2001).

Systems high in sustainability can be taken to be those that aim to make the best use of environmental goods and services whilst not damaging these assets (Altieri, 1995; Pretty, 1995, 1998, 2005; Conway, 1997; Hinchliffe et al, 1999; NRC, 2000; Li Wenhua, 2001; Jackson and Jackson, 2002; Tilman et al, 2002; Uphoff, 2002; McNeely and Scherr, 2003; Swift et al, 2004; Tomich et al, 2004; Gliessman, 2004, 2005; MEA, 2005). The key principles for sustainability are to:

(i) integrate biological and ecological processes such as nutrient cycling, nitrogen fixation, soil regeneration, allelopathy, competition, predation and parasitism into food production processes;
(ii) minimize the use of those non-renewable inputs that cause harm to the environment or to the health of farmers and consumers;
(iii) make productive use of the knowledge and problem-solving skills of farmers, so improving their self-reliance and substituting human capital for costly external inputs;
(iv) make productive use of people's collective capacities to work together to solve common agricultural and natural resource problems, such as for pest, watershed, irrigation, forest and credit management.

The idea of agricultural sustainability, though, does not mean ruling out any technologies or practices on ideological grounds. If a technology works to improve productivity for farmers, and does not cause undue harm to the environment, then it is likely to have some sustainability benefits. Agricultural systems emphasizing these principles also tend to be multi-functional within landscapes and economies (Dobbs and Pretty, 2004; MEA, 2005). They jointly produce food and other goods for farmers and markets, but also contribute to a range of valued public goods, such as clean water, wildlife and habitats, carbon sequestration, flood protection, groundwater recharge, landscape amenity value and leisure/tourism. In this way, sustainability can be seen as both relative and case-dependent, and implies a balance between a wide range of potential agricultural and environmental goods and services.

As a more sustainable agriculture seeks to make the best use of nature's goods and services, so technologies and practices must be locally adapted and fitted to place. These are most likely to emerge from new configurations of social capital, comprising relations of trust embodied in new social organizations, and new horizontal and vertical partnerships between institutions, and human capital comprising leadership, ingenuity, management skills and capacity to innovate. Agricultural systems with high levels of social and human assets are more able to innovate in the face of uncertainty (Chambers et al, 1989; Uphoff, 1998; Bunch and Lopez, 1999; Olsson and Folke, 2001; Pretty and Ward, 2001; Gallagher et al, 2005; Bawden, 2005; Folke et al, 2005). This suggests that there are likely to be many pathways towards agricultural sustainability, and further implies that no single configuration of technologies, inputs and ecological management is more likely to be widely applicable than another. Agricultural sustainability implies the need to fit these factors to the specific circumstances of different agricultural systems.

A common, though erroneous, assumption about agricultural sustainability is that it implies a net reduction in input use, so making such systems essentially extensive (they require more land to produce the same amount of food). Recent empirical evidence shows that successful agricultural sustainability initiatives and projects arise from shifts in the factors of agricultural production (e.g. from use of fertilizers to nitrogen-fixing legumes; from pesticides to an emphasis on natural enemies; from ploughing to zero-tillage). A better concept than an extensive system is one that centres on the intensification of resources – making better use of existing resources (e.g. land, water, biodiversity) and technologies (Conway and Pretty, 1991; Pretty et al, 2000; Buttel, 2003; Tegtmeier and Duffy, 2004; Pretty et al, 2006). The critical question centres on the type of intensification. Intensification using natural, social and human capital assets, combined with the use of best available technologies and inputs (best genotypes and best ecological management) that minimize or eliminate harm to the environment, can be termed sustainable intensification.

Capital Assets for Agricultural Systems

What makes agriculture unique as an economic sector is that it directly affects many of the very assets on which it relies for success. Agricultural systems at all levels rely on the value of services flowing from the total stock of assets that they influence and control, and five types of asset, natural, social, human, physical and financial capital, are now recognized as being important. There are, though, some advantages and misgivings with the use of the term capital. On the one hand, capital implies an asset, and assets should be cared for, protected and accumulated over long periods. On the other, capital can imply easy measurability and transferability. Because the value of something can be assigned a monetary value, then it can appear not to matter if it is lost, as the required money could simply be allocated to purchase another asset, or to transfer it from elsewhere. But nature and its wider values are not so easily replaceable as a commodity (Coleman, 1988; Ostrom, 1990; Putnam, 1993; Flora and Flora, 1996; Costanza et al, 1997; Benton, 1998; Scoones, 1998; Uphoff, 1998, 2002; Pretty, 2003). Nonetheless, as terms, natural, social and human capital are useful in helping to shape concepts around basic questions such as what is agriculture for, and what system works best. The five capitals are defined in the following ways:

1 *Natural capital* produces environmental goods and services, and is the source of food (both farmed and harvested or caught from the wild), wood and fibre; water supply and regulation; treatment, assimilation and decomposition of wastes; nutrient cycling and fixation; soil formation; biological control of pests; climate regulation; wildlife habitats; storm protection and flood control; carbon sequestration; pollination; and recreation and leisure (Costanza et al, 1997; MEA, 2005).
2 *Social capital* yields a flow of mutually beneficial collective action, contributing to the cohesiveness of people in their societies. The social assets comprising social capital include norms, values and attitudes that predispose people to cooperate; relations of trust, reciprocity and obligations; and common rules and sanctions mutually agreed or handed down. These are connected and structured in networks and groups (Flora and Flora, 1996; Pretty, 2003; Cramb and Culaseno, 2003).
3 *Human capital* is the total capability residing in individuals, based on their stock of knowledge skills, health and nutrition (Orr, 1992; Byerlee, 1998; Lieblin et al, 2004; Leeuwis, 2004). It is enhanced by access to services that provide these, such as schools, medical services and adult training. People's productivity is increased by their capacity to interact with productive technologies and with other people. Leadership and organizational skills are particularly important in making other resources more valuable.
4 *Physical capital* is the store of human-made material resources, and comprises buildings, such as housing and factories, market infrastructure, irrigation works, roads and bridges, tools and tractors, communications, and energy and transportation systems, that make labour more productive.
5 *Financial capital* is more of an accounting concept, as it serves as a facilitating role rather than as a source of productivity in and of itself. It represents accumulated claims on goods and services, built up through financial systems that gather savings and issue credit, such as pensions, remittances, welfare payments, grants and subsidies.

As agricultural systems shape the very assets on which they rely for inputs, a vital feedback loop occurs from outcomes to inputs (Worster, 1993). Thus sustainable agricultural systems tend to have a positive effect on natural, social and human capital, whilst unsustainable ones feed back to deplete these assets, leaving fewer for future generations. For example, an agricultural system that erodes soil whilst producing food externalizes costs that others must bear. But one that sequesters carbon in soils through organic matter accumulation helps to mediate climate change. Similarly, a diverse agricultural system that enhances on-farm wildlife for pest control contributes to wider stocks of biodiversity, whilst simplified modernized systems that eliminate wildlife do not. Agricultural systems that offer labour-absorption opportunities, through resource improvements or value-added activities, can boost local economies and help to reverse rural-to-urban migration patterns (Carney, 1998; Dasgupta, 1998; Ellis, 2000; Morison et al, 2005; Pretty et al, 2006).

Any activities that lead to improvements in these renewable capital assets thus make a contribution towards sustainability. However, agricultural sustainability does not require that all assets are improved at the same time. One agricultural system that contributes more to these capital assets than another can be said to be more sustainable, but there may still be trade-offs with one asset increasing as another falls. In practice, though, there are usually strong links between changes in natural, social and human capital (Pretty, 2003), with agricultural systems having many potential effects on all three.

Agriculture is, therefore, fundamentally multifunctional. It jointly produces many unique non-food functions that cannot be produced by other economic sectors so efficiently. Clearly, a key policy challenge, for both industrialized and developing countries, is to find ways to maintain and enhance food production. But a key question is: can this be done whilst seeking both to improve the positive side-effects and to eliminate the negative ones? It will not be easy, as past agricultural development has tended to ignore both the multifunctionality of agriculture and the considerable external costs.

Side-effects and Externalities

There are surprisingly few data on the environmental and health costs imposed by agriculture on other sectors and interests. Agriculture can negatively affect the environment through overuse of natural resources as inputs or through their use as a sink for pollution. Such effects are called negative externalities because they are usually non-market effects and therefore their costs are not part of market prices. Negative externalities are one of the classic causes of market failure whereby the polluter does not pay the full costs of their actions, and therefore these costs are called external costs (Baumol and Oates, 1988; Pretty et al, 2000, 2003a; Dobbs and Pretty, 2004).

Externalities in the agricultural sector have at least four features: (i) their costs are often neglected; (ii) they often occur with a time lag; (iii) they often damage groups whose interests are not well represented in political or decision-making processes; and (iv) the identity of the source of the externality is not always known. For example, farmers generally have few incentives to prevent some pesticides escaping to water-bodies, to the atmosphere and to nearby natural systems as they transfer the full cost of cleaning up the environmental consequences to society at large. In the same way, pesticide manufacturers do not pay the full cost of all their products, as they do not have to pay for any adverse side effects that may occur.

Partly as a result of a lack of information, there is little agreement on the economic costs of externalities in agriculture. Some authors suggest that the current system of economic calculations grossly underestimates the current and future value of natural capital (Abramovitz, 1997; Costanza et al, 1997; Daily, 1997; MEA, 2005). However, such valuation of ecosystem services remains controversial because of methodological and measurement problems (Georghiou et al, 1998; Hanley et al, 1998; Farrow et al, 2000; Carson, 2000) and because of the role monetary values have in influencing public opinions and policy decisions.

What has become clear in recent years is that the success of modern agriculture has masked some significant negative externalities, with environmental and health problems recently costed for Ecuador, China, Germany, the Philippines, the UK and the USA (Pingali and Roger, 1995; Crissman et al, 1998; Waibel et al, 1999; Pretty et al, 2000, 2001, 2003a, 2005; Cuyno et al, 2001; Norse et al, 2001; Buttel, 2003; Tegtmeier and Duffy, 2004; Sherwood et al, 2005). These environmental costs begin to change conclusions about which agricultural systems are the most efficient, and suggest that alternatives which reduce externalities should be sought.

Examples of costs in developing countries include The Philippines, where agricultural systems that do not use pesticides result in greater net social benefits because of the reduction in illnesses among farmers and their families, and the associated treatment costs (Rola and Pingali, 1993; Pingali and Roger, 1995). In China, the externalities of pesticides used in rice systems cause US$1.4 billion of costs per year through health costs to people, and adverse effects on both on- and off-farm biodiversity (Norse et al, 2001). In Ecuador, annual mortality in the remote highlands due to pesticides is among the highest reported anywhere in the world at 21 people per 100,000 people, and so the economic benefits of IPM-based systems that eliminate these effects are increasingly beneficial (Sherwood et al, 2005). In the UK, agricultural externalities have been calculated to be some £1.5 billion per year in the late 1990s (Pretty et al, 2000, 2001). These, though, are exceeded by the environmental costs of transporting food from farm to retail outlet to place of consumption – these 'food miles' in the UK result in a further £3.8 billion of environmental costs per year (Pretty et al, 2005).

These data suggest that all types of agricultural systems impose some kinds of costs on the environment. It is, therefore, impossible to draw a boundary between what is and is not sustainable. If the external costs are high and can be reduced by the adoption of new practices and technologies, then this is a move towards sustainability. Agricultural sustainability is thus partly a matter of judgement, which in turn depends on the comparators and baselines chosen. One system may be said to be more sustainable relative to another if its negative externalities are lower. Monetary criteria do, though, only capture some of the values of agricultural systems and the resources upon which they impinge (Carson, 2000), and so choices may depend on wider questions about the sustainability of farm practices (on farm, in field) and the sustainability of whole landscapes (interactions between agricultural and wild habitats) (Green et al, 2005).

Improving Natural Capital for Agroecosystems

Agricultural sustainability emphasizes the potential benefits that arise from making the best use of both genotypes of crops and animals and their agroecological management. Agricultural sustainability does not, therefore, mean ruling out any technologies or practices on ideological grounds (e.g. genetically modified or organic crops) – provided they improve biological and/or economic productivity for farmers, and do not harm the environment (NRC, 2000; Pretty, 2001; Uphoff, 2002; Nuffield Council on Bioethics, 2004). Agricultural sustainability, therefore, emphasizes the potential dividends that can come from making the best use of the genotypes (G) of crops and animals and the ecological (Ec) conditions under which they are grown or raised. The outcome is a result of this G×Ec interaction (Khush et al, 1998). Agricultural sustainability suggests a focus on both genotype improvements through the full range of modern biological approaches, as well as improved understanding of the benefits of ecological and agronomic management, manipulation and redesign.

Agricultural systems, or agroecosystems, are amended ecosystems (Conway, 1985; Gliessman, 1998; 2005; Olsson and Folke, 2001; Dalgaard et al, 2003; Odum and Barrett, 2004; Swift et al, 2004) that have a variety of different properties (Table 2). Modern agricultural systems have amended some of these properties to increase productivity. Sustainable agroecosystems, by contrast, have to seek to shift some of these properties towards natural systems without significantly trading off productivity. Modern agroecosystems have, for example, tended towards high through-flow systems, with energy supplied by fossil fuels directed out of the system (either deliberately for harvests or accidently through side effects). For a transition towards sustainability, renewable sources of energy need to be maximized, and some energy flows directed to fuel essential internal trophic interactions (e.g. to soil organic matter or to weeds for arable birds) so as to maintain other ecosystem functions (Rydberg and Jansén, 2002; Champion et al, 2003; Haberl et al, 2004; Firbank et al, 2005). All annual crops, though, are derived from opportunists, and so their resource use is inherently different to perennials.

Table 2 *Properties of natural ecosystems compared with modern and sustainable agroecosystems*

Property	*Natural ecosystem*	*Modern agroecosystem*	*Sustainable agroecosystem*
Productivity	Medium	High	Medium (possibly high)
Species diversity	High	Low	Medium
Functional diversity	High	Low	Medium–high
Output stability	Medium	Low–medium	High
Biomass accumulation	High	Low	Medium–high
Nutrient recycling	Closed	Open	Semi-closed
Trophic relationships	Complex	Simple	Intermediate
Natural population regulation	High	Low	Medium–high
Resilience	High	Low	Medium
Dependence on external inputs	Low	High	Medium
Human displacement of ecological processes	Low	High	Low–medium
Sustainability	High	Low	High

Source: Gliessman, 2005

Modern agriculture has also come to rely heavily on nutrient inputs obtained from or driven by fossil fuel-based sources. Nutrients are also used inefficiently, and together with certain products (e.g. ammonia, nitrate, methane, carbon dioxide), are lost to the environment. For sustainability, nutrient leaks need to be reduced to a minimum, recycling and feedback mechanisms introduced and strengthened, and nutrients and materials diverted to capital accumulation. Agroecosystems are considerably more simplified than natural ecosystems, and loss of biological diversity (to improve crop and livestock productivity) results in the loss of some ecosystem services, such as pest and disease control (Gallagher et al, 2005). For sustainability, biological diversity needs to be increased to recreate natural control and regulation functions, and to manage pests and diseases rather than seeking to eliminate them. Mature ecosystems are now known to be not stable and unchanging, but in a state of dynamic equilibrium that buffers against large shocks and stresses. Modern agroecosystems have weak resilience, and for transitions towards sustainability need to focus on structures and functions that improve resilience (Holling et al, 1998; Folke et al, 2005).

But converting an agroecosystem to a more sustainable design is complex, and generally requires a landscape or bioregional approach to restoration or management (Kloppenburg et al, 1996; Higgs, 2003; Jordan, 2003; Odum and Barrett, 2004; Swift et al, 2004; Terwan et al, 2004). An agroecosystem is a bounded system designed to produce food and fibre, yet it is also part of a wider landscape at which scale a number of ecosystem functions are important (Gliessman, 2005). For sustainability, interactions need to be developed between agroecosystems and whole landscapes of other farms and non-farmed or wild habitats (e.g. wetlands, woods, riverine habitats), as well as social systems of food procurement. Mosaic landscapes with a variety of farmed and non-farmed habitats are known to be good for birds as well as farms (Bignall and McCracken, 1996; Shennan et al, 2005; Woodhouse et al, 2005).

There are several types of resource-conserving technologies and practices that can be used to improve the stocks and use of natural capital in and around agro-ecosystems. These are:

1 *Integrated pest management*, which uses ecosystem resilience and diversity for pest, disease and weed control, and seeks only to use pesticides when other options are ineffective (e.g. Lewis et al, 1997; Gallagher et al, 2005; Herren et al, 2005).
2 *Integrated nutrient management*, which seeks both to balance the need to fix nitrogen within farm systems with the need to import inorganic and organic sources of nutrients, and to reduce nutrient losses through erosion control (Crews and Peoples, 2004; Leach et al, 2004).
3 *Conservation tillage*, which reduces the amount of tillage, sometime to zero, so that soil can be conserved and available moisture used more efficiently (Petersen et al, 2000; Holland, 2004).
4 *Agroforestry*, which incorporates multifunctional trees into agricultural systems, and collective management of nearby forest resources (Leakey et al, 2005).
5 *Aquaculture*, which incorporates fish, shrimps and other aquatic resources into farm systems, such as into irrigated rice fields and fish ponds, and so leads to increases in protein production (Bunting, 2007).
6 *Water harvesting* in dryland areas, which can mean formerly abandoned and degraded lands can be cultivated, and additional crops grown on small patches of irrigated land owing to better rain water retention (Pretty, 1995; Reij, 1996).
7 *Livestock integration* into farming systems, such as dairy cattle, pigs and poultry, including using zero-grazing cut and carry systems (Altieri, 1995).

Many of these individual technologies are also multifunctional (Pretty, 1995; Lewis et al, 1997). This implies that their adoption should mean favourable changes in several components of the farming system at the same time. For example, hedgerows and alley crops encourage predators and act as windbreaks, so reducing soil erosion. Legumes introduced into rotations fix nitrogen, and also act as a break crop to prevent carry-over of pests and diseases. Grass contour strips slow surface water run-off, encourage percolation to groundwater, and can be a source of fodder for livestock. Catch crops prevent soil erosion and leaching during critical periods, and can also be ploughed in as a green manure. The incorporation of green manures not only provides a readily available source of nutrients for the growing crop but also increases soil organic matter and hence water retentive capacity, further reducing susceptibility to erosion.

Although many resource-conserving technologies and practices are currently being used, the total number of farmers using them worldwide is still relatively small. This is because their adoption is not a costless process for farmers. They cannot simply cut their existing use of fertilizer or pesticides and hope to maintain outputs, so making operations more profitable. They also cannot simply introduce a new productive element into their farming systems, and hope it succeeds. These transition costs arise for several reasons. Farmers must first invest in learning (Orr, 1992; Röling and Wagermakers, 1997; Bentley et al, 2003; Lieblin et al, 2004; Bawden, 2005; Chambers, 2005). As recent and current policies have tended to promote specialized, non-adaptive systems with a lower innovation capacity, so farmers have to spend time learning about a greater diversity of practices and measures (Gallagher et al, 2005). Lack of information and management skills is, therefore, a major barrier to the adoption of sustainable agriculture. During the transition period, farmers must experiment more, and so incur the costs of making mistakes as well as of acquiring new knowledge and information.

The on-farm biological processes that make sustainable agroecosystems productive also take time to become established. These include the rebuilding of depleted natural buffers of predator stocks and wild host plants; increasing the levels of nutrients; developing and exploiting microenvironments and positive interactions between them; and the establishment and growth of trees. These higher variable and capital investment costs must be incurred before returns increase. Examples include costs for: labour in the construction of soil and water conservation measures; the planting of trees and hedgerows; pest and predator monitoring and management; fencing of paddocks; the establishment of zero-grazing units; and the purchase of new technologies, such as manure storage equipment or global positioning systems for tractors.

It has also been argued that farmers adopting more sustainable agroecosystems are internalizing many of the agricultural externalities associated with intensive farming, and so could be compensated for effectively providing environmental goods and services. Providing such compensation or incentives would be likely to increase the adoption of resource conserving technologies (Dobbs and Pretty, 2004). Nonetheless, periods of lower yields seem to be more apparent during conversions of industrialized agroecosystems. There is growing evidence to suggest that most pre-industrial and modernized farming systems in developing countries can make rapid transitions to both sustainable and productive farming.

Social Learning and Asset Building

The term participation is now part of the normal language of most development and conservation agencies. It has become such a fashion that almost everyone says that it is part of their work. This has created many paradoxes, as it is easy to misinterpret the term. In conventional development, participation has commonly centred on encouraging local people to contribute their labour in return for food, cash or materials. But material incentives distort perceptions, create dependencies, and give the misleading impression that local people are supportive of externally driven initiatives. When little effort is made to build local interests and capacity, then people have no stake in maintaining structures or practices once the flow of incentives stops. If people do not cross a cognitive frontier, then there will be no ecological literacy.

The dilemma for authorities is that they both need and fear people's participation. They need people's agreement and support, but they fear that wider and open-ended involvement is less controllable. But if this fear permits only stage-managed forms of participation, then distrust and greater alienation are the most likely outcomes. Participation can mean finding something out and proceeding as originally planned. Alternatively, it can mean developing processes of collective learning that change the way that people think and act. The many ways that organizations interpret and use the term participation range from passive participation, where people are told what is to happen and act out predetermined roles, to self-mobilization, where people take initiatives independently of external institutions (Pretty, 1995).

Agricultural development often starts with the notion that there are technologies that work, and so it is just a matter of inducing or persuading farmers to adopt them (Leeuwis, 2004). But the problem is that the imposed models look good at first, and then tend to fade away (Kerr et al, 1999). Alley cropping, an agroforestry system comprising rows of nitrogen-fixing trees or bushes separated by rows of cereals, has long been the focus of research. Many productive and sustainable systems, needing few or no external inputs, have been developed. They stop erosion, produce food and wood, and can be cropped over long periods. But the problem is that very few farmers have adopted these systems as designed – they appear to have been produced as suitable largely only for research stations, with their plentiful supplies of labour and resources and standardized soil conditions.

It is critical that sustainable agriculture and conservation management do not prescribe concretely defined sets of technologies and practices. This only serves to restrict the future options of farmers and rural people. As conditions change and as knowledge changes, so must the capacity of farmers and communities be enhanced to allow them to change and adapt too. Agricultural sustainability should not imply simple models or packages to be imposed. Rather it should be seen as a process of social learning, and emergent technologies fitted to specific local circumstances. This centres on building the capacity of farmers and their communities to learn about the complex ecological and biophysical complexity in their fields and farms, and then to act on this information. The process of learning, if it is socially embedded and jointly engaged upon, provokes changes in behaviour and can bring forth a new world (Maturana and Varela, 1992).

What lessons have we learned from programmes that successfully promote social learning and sustainable natural resource management? The first is that sustainability is an emergent property of systems high in social, human and natural capital. When these assets are in decline, then we are retreating from sustainability. Next is the recognition that farmers can improve their agroecological understanding of the complexities of their farms and related ecosystems, and that new information can lead to improved agricultural outcomes. In turn, increased understanding is also an emergent property, derived in particular from farmers engaging in their own experimentation, supported by scientists and extensionists, leading to the development of novel technologies and practices. These are more likely to spread from farmer to farmer, and from group to group. These conclusions strongly suggest that social learning processes should become an important focus for all agricultural and natural resource management programmes, and that professionals should make every effort to appreciate both the complementarity of such social processes with sustainable technology development and spread, and the subtlety and care required in their implementation.

What can be done both to encourage the greater adoption of group-based programmes for environmental improvements, and to identify the necessary support for groups to evolve to maturity, and thence to spread and connect with others? Clearly, international agencies, governments, banks and non-government organizations should invest more in social and human capital creation. It is not costless to build human capital and establish new forms of organization and social capital. The main danger lies in being satisfied with any degree of partial progress, and so not going far enough. Of course, group-based approaches alone are not sufficient conditions for achieving sustainable natural resource management. Policy reform is an additional requirement for shaping the wider context, in order to make it more favourable to the emergence and sustenance of local groups. This has clearly worked in countries such as India, Sri Lanka and Australia.

One way to ensure the stability of social connectedness is for groups to work together by federating to influence district, regional or even national bodies. This can open up economies of scale to bring greater economic and ecological benefits. The emergence of such federated groups with strong leadership also makes it easier for government and non-governmental organizations to develop direct links with poor and formerly excluded groups, although if these groups were dominated by the wealthy, the opposite would be true. This could result in greater empowerment of poor households, as they draw on public services more efficiently. Such interconnectedness between groups is more likely to lead to improvements in natural resources than regulatory schemes alone (Röling and Wagemakers, 1997; Dobbs and Pretty, 2004).

But this raises further questions. How, too, can policy makers protect existing programmes in the face of new threats? What will happen to state–community relations when social capital in the form of local associations and their federated bodies spreads to very large numbers of people? Will the state colonize these groups, or will new broad-based forms of democratic governance emerge? Important questions also relate to the groups themselves. Good programmes may falter if individuals start to 'burn out', feeling that investments in social capital are no longer paying. It is vitally important that policy makers and practitioners continue to seek ways to provide support for the processes that both help groups to form, and help them mature along the lines that local people desire and need, and from which natural environments will benefit.

There are also persistent concerns that the establishment of new community institutions and users' groups may not always benefit the poor. There are signs that they can all too easily become a new rhetoric without fundamentally improving equity and natural resources. If, for example, joint forest management becomes the new order of the day for foresters, then there is a very real danger that some will coerce local people into externally run groups so that targets and quotas are met. This is an inevitable part of any transformation process. The old guard adopts the new language, implies they were doing it all the time, and nothing really changes. But this is not a reason for abandoning the new. Just because some groups are captured by the wealthy, or are run by government staff with little real local participation, does not mean that all are fatally flawed. What it does show clearly is that the critical frontiers are inside us. Transformations must occur in the way we all think if there are to be real and large-scale transformations in the land and the lives of people.

Effects of Sustainable Agriculture on Yields

One persistent question regarding the potential benefits of more sustainable agroecosystems centres on productivity trade-offs. If environmental goods and services are to be protected or improved, what then happens to productivity? If it falls, then more land will be required to produce the same amount of food, thus resulting in further losses of natural capital (Green et al, 2005). As indicated earlier, the challenge is to seek sustainable intensification of all resources in order to improve food production. In industrialized farming systems, this has proven to be impossible to do with organic production systems, as food productivity is lower for both crop and livestock systems (Lampkin and Padel, 1994; Caporali et al, 2003). Nonetheless, there are now some 3Mha of agricultural land in Europe managed with certified organic practices. Some have led to lower energy use (though lower yields too); others to better nutrient retention, and some greater nutrient losses (Dalgaard et al, 1998, 2002; Løes and Øgaard, 2003; Gosling and Shepherd, 2004), and some to greater labour absorption (Morison et al, 2005).

Many other farmers have adopted integrated farming practices, which represent a step or several steps towards sustainability. What has become increasingly clear is that many modern farming systems are wasteful, as integrated farmers have found they can cut down many purchased inputs without losing out on profitability (EA, 2005). Some of these cuts in use are substantial, others are relatively small. By adopting better targeting and precision methods, there is less wastage and so more benefit to the environment. They can then make greater cuts in input use once they substitute some regenerative technologies for external inputs, such as legumes for inorganic fertilizers or predators for pesticides. Finally, they can replace some or all external inputs entirely over time once they have learned their way into a new type of farming characterized by new goals and technologies (Pretty and Ward, 2001).

What is clear is that resource-conserving and regenerative technologies are spreading. In Denmark, some 150 farms have in-field weather stations to help predict disease outbreaks in potatoes, leading to cuts in fungicide use, with some growers able to postpone first applications for five or more weeks. In the UK, some 150,000 hectares of cereal farms were computer-mapped in the early 2000s, enabling inputs to be targeted more precisely and the total use of pesticide and fertilizer to be cut. Also in the UK, three-quarters of crops grown in glasshouses use natural predators to control pests rather than pesticides. In France, there are 700 farms in the national network researching and implementing 'agriculture durable'. In the state of Baden-Württemberg in southern Germany, 100,000 farms are using sustainable practices and technologies, though not all are integrated at the whole farm level. In Australia, one third of all farmers are members of Landcare groups. The organic revolution also continues, with demand from consumers growing, and the number of farmers converted entirely to organic practices in industrialized countries continues to grow rapidly.

However, it is in developing countries that some of the most significant progress towards sustainable agroecosystems has been made in the past decade (Uphoff, 2002; McNeely and Scherr, 2003; Pretty et al, 2003b). The largest study comprised the analysis of 286 projects in 57 countries (Pretty et al, 2006). This involved the use of both questionnaires and published reports by projects to assess changes over time. As in earlier research (Pretty et al, 2003b), data were triangulated from several sources, and cross-checked by external reviewers and regional experts. The study involved analysis of projects sampled once in time ($n = 218$) and those sampled twice over a 4-year period ($n = 68$). Not all proposed cases were accepted for the dataset, and rejections were based on a strict set of criteria. As this was a purposive sample of 'best practice' initiatives, the findings are not representative of all developing country farms.

Table 3 contains a summary of the location and extent of the 286 agricultural sustainability projects across the eight categories of FAO farming systems (Dixon et al, 2001) in the 57 countries. In all, some 12.6 million farmers on 37 million hectares were engaged in transitions towards agricultural sustainability in these 286 projects. This is just over 3 per cent of the total cultivated area (1136 million ha) in developing countries. The largest number of farmers was in wetland rice-based systems, mainly in Asia (category 2), and the largest area was in dualistic mixed systems, mainly in southern Latin America (category 6). This study showed that agricultural sustainability was spreading to more farmers and hectares. In the 68 randomly re-sampled projects from the original study, there was a 54 per cent increase over the four years in the number of farmers, and 45 per cent in the number of hectares. These resurveyed projects comprised 60 per cent of the farmers and 44 per cent of the hectares in the original sample of 208 projects.

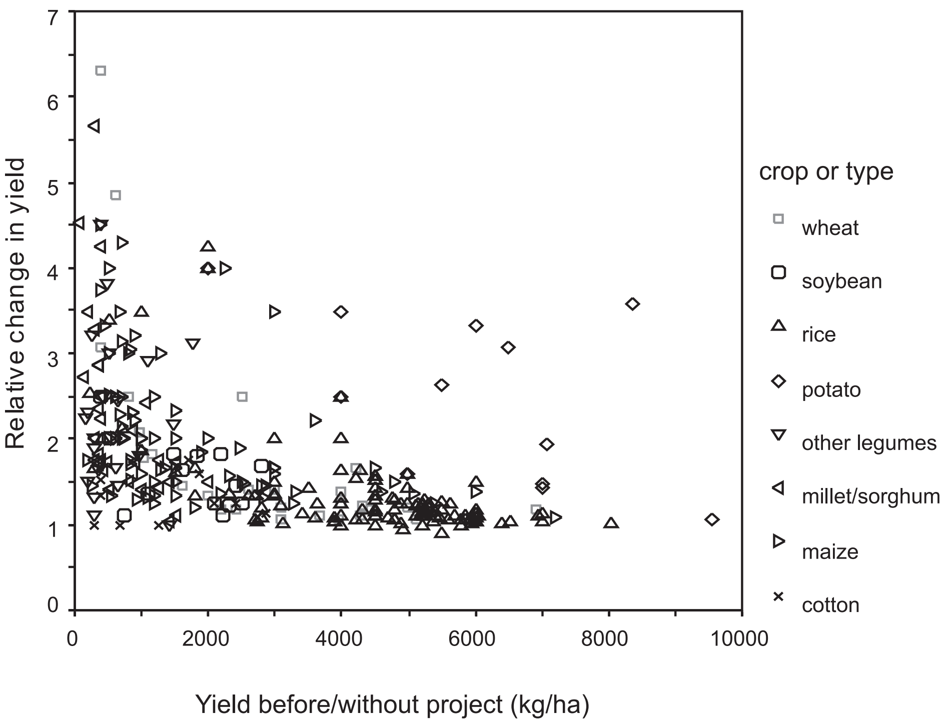
Table 3 *Summary of adoption and impact of agricultural sustainability technologies and practices on 286 projects in 57 countries*

FAO farm system category[1]	*Number of farmers adopting*	*Number of hectares under sustainable agriculture*	*Average % increase in crop yields*[2]
1. Smallholder irrigated	177,287	357,940	129.8 (±21.5)
2. Wetland rice	8,711,236	7,007,564	22.3 (±2.8)
3. Smallholder rainfed humid	1,704,958	1,081,071	102.2 (±9.0)
4. Smallholder rainfed highland	401,699	725,535	107.3 (±14.7)
5. Smallholder rainfed dry/cold	604,804	737,896	99.2 (±12.5)
6. Dualistic mixed	537,311	26,846,750	76.5 (±12.6)
7. Coastal artisanal	220,000	160,000	62.0 (±20.0)
8. Urban-based and kitchen garden	207,479	36,147	146.0 (±32.9)
All projects	12,564,774	36,952,903	79.2 (±4.5)

[1] Farm categories from Dixon et al (2001).
[2] Yield data from 360 crop-project combinations; reported as % increase (thus a 100% increase is a doubling of yields). Standard errors in brackets.

For the 360 reliable yield comparisons from 198 projects, the mean relative yield increase was 79 per cent across the very wide variety of systems and crop types. However, there was a wide spread in results (Figure 3). While 25 per cent of projects reported relative yields greater than 2.0 (i.e. 100 per cent increase), half of all the projects had yield increases of between 18 per cent and 100 per cent. The geometric mean is a better indicator of the average for such data with a positive skew, but this still shows a 64 per cent increase in yield. These sustainable agroecosystems also have positive side effects, helping to build natural capital, strengthen communities (social capital) and develop human capacities (Ostrom, 1990; Pretty, 2003). Examples of positive side effects recently recorded in various developing countries include:

- improvements to natural capital, including increased water retention in soils, improvements in water table (with more drinking water in the dry season), reduced soil erosion combined with improved organic matter in soils, leading to better carbon sequestration, and increased agro-biodiversity;
- improvements to social capital, including more and stronger social organizations at local level, new rules and norms for managing collective natural resources, and better connectedness to external policy institutions;
- improvements to human capital, including more local capacity to experiment and solve own problems; reduced incidence of malaria in rice–fish zones,



Note: Only field crops with $n > 9$ are shown.

Figure 3 *Relationship between relative changes in crop yield after (or with project) to yield before (or without project)*

> increased self-esteem in formerly marginalized groups, increased status of women, better child health and nutrition, especially in dry seasons, and reversed migration and more local employment.

What we do not know, however, is the full economic benefits of these spin-offs. In many industrialized countries, agriculture is now assumed to contribute very little to GDP, leading many commentators to assume that agriculture is not important for modernized economies (NRC, 2000). But such a conclusion is a function of the fact that too few measures are being made of the positive side effects of agriculture (MEA, 2005). In poor countries, where financial support is limited and markets weak, then people rely even more on the value they can derive from the natural environment and from working together to achieve collective outcomes.

Effects of Sustainable Agriculture on Pesticide Use and Yields

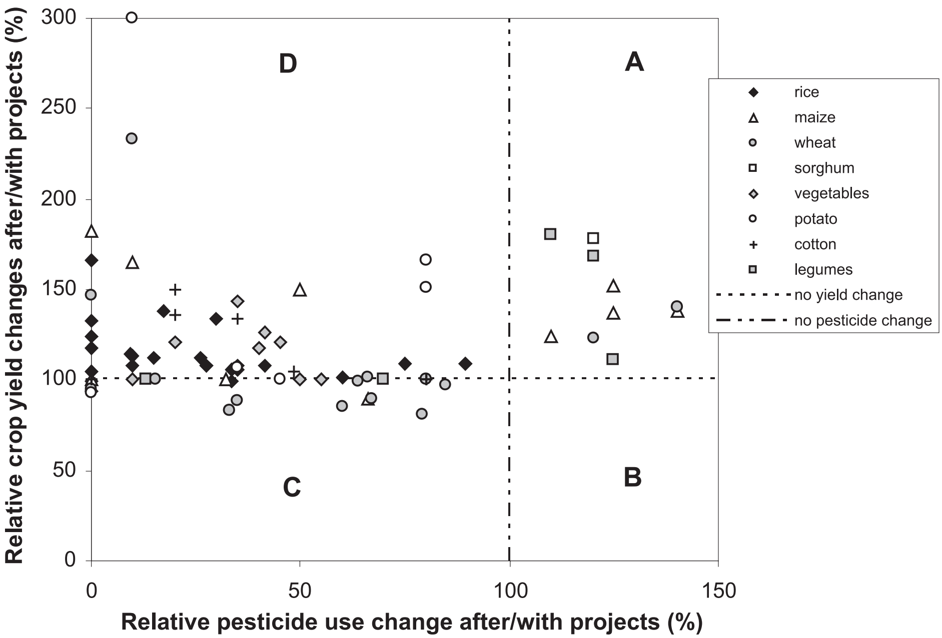
Recent integrated pest management (IPM) programmes, particularly in developing countries, are beginning to show how pesticide use can be reduced and pest management practices can be modified without yield penalties (Heong et al, 1999; Brethour and Weerskink, 2001; Wilson and Tisdell, 2001; Gallagher et al, 2005; Herren et al, 2005; Pretty and Waibel, 2005). In principle, there are four possible trajectories of impact if IPM is introduced:

1 both pesticide use and yields increase (A);
2 pesticide use increases but yields decline (B);
3 both pesticide use and yields fall (C);
4 pesticide use declines, but yields increase (D).

The assumption in modern agriculture is that pesticide use and yields are positively correlated. For IPM, the trajectory moving into sector A is therefore unlikely but not impossible, for example in low-input systems. What is expected is a move into sector C. While a change into sector B would be against economic rationale, farmers are unlikely to adopt IPM if their profits would be lowered. A shift into sector D would indicate that current pesticide use has negative yield effects or that the amount saved from pesticides is reallocated to other yield increasing inputs. This could be possible with an excessive use of herbicides or when pesticides cause outbreaks of secondary pests, such as observed with the brown plant hopper in rice (Kenmore et al, 1984).

Figure 4 shows data from 62 IPM initiatives in 26 developing and industrialized countries (Australia, Bangladesh, China, Cuba, Ecuador, Egypt, Germany, Honduras, India, Indonesia, Japan, Kenya, Laos, Nepal, the Netherlands, Pakistan, the Philippines, Senegal, Sri Lanka, Switzerland, Tanzania, Thailand, the UK, the USA, Vietnam and Zimbabwe) (Pretty and Waibel, 2005). The 62 IPM initiatives have some 5.4 million farm households on 25.3Mha. The evidence on pesticide use is derived from data on both the number of sprays per hectare and the amount of active ingredient used per hectare. This analysis does not include recent evidence on the effect of some genetically modified crops, some of which result in reductions in the use of herbicides (Champion et al, 2003) and pesticides (Nuffield Council on Bioethics, 2004), and some of which have led to increases (Benbrook, 2003).

There is only one sector B case reported in recent literature (Feder et al, 2004). Such a case has recently been reported from Java for rice farmers. The cases in sector C, where yields fall slightly while pesticide use falls dramatically, are mainly cereal farming systems in Europe, where yields typically fall to some 80 per cent of current levels while pesticide use is reduced to 10–90 per cent of current levels (Pretty, 1998; Röling and Wagemakers, 1997). Sector A contains 10 projects where



Note: Data from 80 crop combinations, 62 projects, 26 countries.

Figure 4 *Association between pesticide use and crop yields*

total pesticide use has indeed increased in the course of IPM introduction. These are mainly in zero-tillage and conservation agriculture systems, where reduced tillage creates substantial benefits for soil health and reduces off-site pollution and flooding costs. These systems usually require an increased use of herbicides for weed control (de Freitas, 1999), although there are some examples of organic zero-tillage systems (Petersen et al, 2000). Over 60 per cent of the projects are in category D where pesticide use declines and yields increase. While pesticide reduction is to be expected, as farmers substitute pesticides by information, yield increases induced by IPM are a more complex issue. It is likely, for example, that farmers who receive good quality field training will not only improve their pest management skills but also become more efficient in other agronomic practices such as water, soil and nutrient management. They can also invest some of the cash saved from pesticides in other inputs such as higher quality seeds and inorganic fertilizers.

Effects on Carbon Balances

The 1997 Kyoto Protocol to the UN Framework Convention on Climate Change established an international policy context for the reduction of carbon emissions and increases in carbon sinks in order to address the global challenge of anthropogenic interference with the climate system. It is clear that both emission reductions and sink growth will be necessary for mitigation of current climate change trends (Watson et al, 2000; IPCC, 2001, 2007; Royal Society, 2001; Swingland, 2003; Oelbermann et al, 2004). A source is any process or activity that releases a greenhouse gas, or aerosol or a precursor of a greenhouse gas into the atmosphere, whereas a sink is a mechanism that removes these from the atmosphere. Carbon sequestration is defined as the capture and secure storage of carbon that would otherwise be emitted to or remain in the atmosphere. Agricultural systems emit carbon through the direct use of fossil fuels in food production, the indirect use of embodied energy in inputs that are energy-intensive to manufacture, and the cultivation of soils and/or soil erosion resulting in the loss of soil organic matter. Agriculture also contributes to climate change through emissions of methane from irrigated rice systems and ruminant livestock. The direct effects of land use and land use change (including forest loss) have led to a net emission of 1.7Gt C yr^{-1} in the 1980s and 1.6Gt C yr^{-1} in the 1990s (Watson et al, 2000; Bellamy et al, 2005).

On the other hand, agriculture can also be an accumulator of carbon when organic matter is accumulated in the soil, and when above-ground biomass acts either as a permanent sink or is used as an energy source that substitutes for fossil fuels and so avoids carbon emissions. There are three main mechanisms and 21 technical options (Table 4) through which positive actions can be taken by farmers by:

A increasing carbon sinks in soil organic matter and above-ground biomass;
B avoiding carbon dioxide or other greenhouse gas emissions from farms by reducing direct and indirect energy use;
C increasing renewable energy production from biomass that either substitutes for consumption of fossil fuels or replaces inefficient burning of fuelwood or crop residues, and so avoids carbon emissions.

Social Outcomes in Developing Countries

At some locations, agroecological approaches have had a significant impact on labour markets. Some practices result in increased on-farm demand for labour (e.g. water harvesting in Niger), whilst others actually reduce labour demand (e.g. zero-tillage in Brazil). Some result in the opening up of whole new seasons for agricultural production, particularly in dryland contexts, through improved harvesting of rainfall, leading to much greater demand for labour. Migration reversals can also occur when wage labour opportunities increase as part of the project (e.g. watershed improvements), when more productive agriculture leads to higher wages and employment, when there are higher returns to agriculture, and when there are

Table 4 *Mechanisms for increasing carbon sinks and reducing CO_2 and other greenhouse gas emissions in agricultural systems*

Mechanism A. Increase carbon sinks in soil organic matter and above-ground biomass
• Replace inversion ploughing with conservation- and zero-tillage systems
• Adopt mixed rotations with cover crops and green manures to increase biomass additions to soil
• Adopt agroforestry in cropping systems to increase above-ground standing biomass
• Minimize summer fallows and periods with no ground cover to maintain soil organic matter stocks
• Use soil conservation measures to avoid soil erosion and loss of soil organic matter
• Apply composts and manures to increase soil organic matter stocks
• Improve pasture/rangelands through grazing, vegetation and fire management both to reduce degradation and increase soil organic matter
• Cultivate perennial grasses (60–80% of biomass below ground) rather than annuals (20% below ground)
• Restore and protect agricultural wetlands
• Convert marginal agricultural land to woodlands to increase standing biomass of carbon
Mechanism B. Reduce direct and indirect energy use to avoid greenhouse gas emissions (CO_2, CH_4 and N_2O)
• Conserve fuel and reduce machinery use to avoid fossil-fuel consumption
• Use conservation or zero-tillage to reduce CO_2 emissions from soils
• Adopt grass-based grazing systems to reduce methane emissions from ruminant livestock
• Use composting to reduce manure methane emissions
• Substitute biofuel for fossil fuel consumption
• Reduce the use of inorganic N fertilizers (as manufacture is highly energy-intensive), and adopt targeted- and slow-release fertilizers
• Use integrated pest management to reduce pesticide use (avoid indirect energy consumption)
Mechanism C. Increase biomass-based renewable energy production to avoid carbon emissions
• Cultivate annual crops for biofuel production, such as ethanol from maize and sugar cane
• Cultivate annual and perennial crops, such as grasses and coppiced trees, for combustion and electricity generation, with crops replanted each cycle for continued energy production
• Use biogas digesters to produce methane, so substituting for fossil fuel sources
• Use improved cookstoves to increase efficiency of biomass fuels

Source: Pretty et al, 2002

overall improvements in village conditions, such as infrastructure and services. Improvements in urban gardening have led to increases in employment (Funes et al, 2002).

There are several documented cases where these approaches have helped to reverse seasonal or even long-term migration. In the Guinope and Cantarranas regions of Honduras, families returned from the capital city to take up labour opportunities brought by rural economic growth centred on improved agricultural productivity. In India, seasonal migration from a number of rainfed projects (e.g. in Maharashtra, Gujarat and Tamil Nadu) declined as sufficient water becomes available to crop in the dry season, with women in particular benefiting from being able to remain at home all year. In Niger, young men have been able to form labour-societies to meet the demand for water-harvesting construction, rather than migrate to the coast for work (Reij, 1996; Bunch and Lopez, 1999; Pretty, 2002; Kabore and Reij, 2004)

However, in some locations increasing labour requirements may be an impediment to adoption, and farmers may actually desire labour-saving technologies and practices. All transformations in agricultural systems are costly, thus always mitigating against the poorest households and economies. Given the appropriate institutional conditions, poor households may, however, be able to make use of new configurations of human and social capital to make more productive use of natural capital and available technologies. In some areas, but not all, this also means an increase in on-farm labour requirements. Within households, such additional labour is often supplied by women rather than men.

Where labour is scarce, such as in HIV-affected populations, or where women suffer a particularly heavy double load of domestic and agricultural labour, or when there are significant off-farm labour opportunities (e.g. 52 per cent of rural household income in Latin America comes from non-agricultural employment) then technologies for agricultural sustainability will either need to emphasize labour saving or result in sufficiently high productivity gains that labour can be hired. Examples of the former include zero-tillage using herbicides for weed control in Brazil and Argentina, and legumes as green manures and cover crops in Central America. Examples of the latter include raised-bed vegetable technology for women's groups in East Africa and fish-raising in paddy fields in South Asia.

What we do not know is how internal labour markets will affect incentives to work in agriculture and rural regions, and how best to promote regional rural development based on agricultural intensification. Sustainable agriculture has the potential directly and indirectly to influence the health of rural people. In the first instance, improved food supply throughout the year has a fundamental impact on health, which in turn allows adults to be more productive, and children to attend school and still be able to concentrate on learning. In Kenya, for example, the simple technology of double-dug beds has improved domestic food supply for several tens of thousands of households by producing a year-round supply of vegetables. It is children who have been noted as major beneficiaries.

In some cases, a more sustainable agriculture can also help to remove threats to health in the environment – such as consumption of mosquito larva by fish in rice fields – with measurable reductions in malaria incidence recorded in China. In Jiangsu Province, there has been rapid growth of rice aquaculture: from about

5000ha in 1994 to 117,000ha of rice–fish, rice–crab and rice–shrimp systems. Rice yields have increased by 10–15 per cent, but the greatest dividend is in protein: each mu (one fifteenth of a hectare) can produce 50kg of fish (Li Wenhua, 2001). Additional benefits come from reduced insecticide use, and measured reductions in malaria incidence owing to fish predation of mosquito larvae.

Sustainable agriculture can also have an indirect effect on reproductive health. Where women are organized into groups, such as for microfinance delivery (credit and savings), livestock raising or watershed development, such social capital creation offers opportunities or 'entry points' for other sectors to interact closely with women. In Ecuador, for example, the World Neighbors (WN) programme working with remote rural communities on sustainable agriculture and natural resource management made a substantial impact on family planning. WN actively compared two types of programme in Guaranda canton, Bolivar Province, by working in six communities that only received health input, and another six that received an integrated programme involving soil and water conservation, green manures, vegetable gardening and farmer-experimentation with barley, wheat, maize and potato varieties, combined with group formation. The health interventions yielded few results. But the integrated approach brought pronounced changes in attitudes and values. Contraceptive use in these communities was double that in the 'health only' villages. The family planning clinic, on the verge of closure in 1992, provided 18,000 consultations in 1998 (Ruddell, 1995; Hinchcliffe et al, 1999; Uphoff, 2002).

In Nepal, World Neighbors also found that reproductive health and family planning were not effective entry points. Instead, women's reproductive health, status, work and fertility could be better addressed by forming and working with women's savings and credit groups that could participate in planning a wide range of development activities. Confident groups with better literacy, income and food security were able to challenge traditional roles and norms, leading to capacity to deal directly with reproductive health.

In certain circumstances, sustainable agriculture practices appear to be currently more accessible to larger farmers – particularly the zero-tillage systems in Argentina, Brazil and Paraguay. However, evidence from Paraguay and Brazil also suggests that larger numbers of small farmers are now adopting and adapting elements of these practices. It is important to note that adoption of conservation agriculture by large farmers may still result in significant regional change: 'zero-tillage has been a major factor in changing the top-down nature of agricultural services to farmers towards a participatory, on-farm approach' (John Landers, pers. comm.). But in other contexts, sustainable agriculture has first been adopted by small farmers, and is only now spreading to larger ones once they have seen the initial success. In Bangladesh, the rice–fish and rice–IPM technologies were adopted by very small farmers first, with larger farmers attracted only when success had been proven.

Can agroecological approaches result in improvements in livelihoods for landless families and the core poor? There are three possibilities: improvements to labour markets, improved access to land through land reform, or changed social norms that encourage greater equity and sharing. The first of these seems more likely than the others – though as noted above, some sustainable agriculture applications are favoured by farm families precisely because they reduce labour requirements. There is some evidence that social capital formation can result in new equitable arrangements within communities. Landless families, for example, have been given new opportunities to join farmers' groups in western and central Kenya. Such changes cannot be directly attributed to sustainable agriculture – rather it is due to changes in values and norms arising from new configurations of local social capital.

Is There a Place for Genetic Modification?

Only a few years after the development of the first genetically modified crops for agriculture, opinions on benefits and risk remain sharply divided. Some argue that genetically modified organisms are safe and essential for world progress; others state they are not needed, and hold too many risks. The first group believes that media manipulation and scaremongering are limiting useful technologies; the second that scientists, private companies and regulators are understating hazards for the sake of economic returns.

Neither view is entirely correct, for one simple reason. Genetically modified organisms are not a single, simple technology (Pretty, 2001; GM Science Review, 2003; Nuffield Council on Bioethics, 2004). Each product brings different potential benefits for different stakeholders; each poses different environmental and health risks. It is, therefore, useful to distinguish between different generations of genetically modified technologies. The first generation technologies came into commercial use in the late 1990s and early 2000s, and have tended not to bring distinct consumer benefits, one reason why there is so much current public opposition. The realization of promised benefits to farmers and the environment has only been patchy. First generation technologies include herbicide-tolerant crops, insect-resistant crops, long-life tomatoes, bacteria in containment for the production of cheese and washing-powder enzymes, and flowers with amended colour.

The second generation technologies comprise those already developed and tested, but not yet commercially released on a large scale, either because of uncertainties over the stability of the technology itself, or over concerns for potential environmental risks. Some of these applications are likely to bring more public and consumer benefits, and include a range of medical applications. These include viral resistance in rice, cassava, papaya, sweet potatoes, peppers; nematode resistance in various cereal and other crops, such as banana and potato; frost tolerance in strawberry, *B.t.* clover, trees with reduced lignin, vitamin A rice and bio-pharming with crops and animals for pharmaceuticals.

The third generation technologies are those that are still far from market, but generally require a better understanding of whole gene complexes that control such traits as drought- or salt-tolerance, and nitrogen-fixation. These are likely to bring more explicit consumer benefits than the first generation. These include stress tolerance in cereals, such as thermo, salt- and heavy metal-tolerance; drought resistance; physiological modifications of crops and trees to increase efficiency of resource use (nutrients, water, light) or delaying of ageing in leaves; neutraceuticals (crops boosted with vitamins/minerals); vaccine crops (such as banana and potato); designer crops modified to produce oils or plastics; the development of new markers to replace antibiotics; and legumes with increased tannins for bloat control in cattle.

The first generation technologies have tended only to provide substantial private benefits for the companies producing them and farmers using them. Many of the later generation genetically modified organisms are, by contrast, more multifunctional and public-good oriented, although like all technologies clearly none are without risk. Modifications of crops with low value in rotations, such as legumes and oats, will make them more attractive to farmers because of high protein and energy content. Others will be more efficient in nitrogen use, so reducing nitrate leaching, or modifications of rhizobia could improve the nitrogen-fixing capacity of a wide range of crops. Both options would reduce the need to use nitrogen fertilizers.

Although the pace of change in the development of GM has provoked many debates, there has been relatively little said about the potential benefits for developing countries. Many concerns are about important indirect effects, such as the growing centralization of world agriculture. These represent structural changes in agriculture in which GM crops are a contributor to change, but not necessarily the driver. These contested positions raise important questions. Will GM crops contribute to the further promotion of technological approaches to agricultural development? Could such technologies bring environmental benefits, and so promote sustainability? Are GM technologies essential for feeding a hungry world, or is hunger more a result of poverty, with poor consumers and farmers unable to afford modern, expensive technologies?

Some say emphatically yes, often raising the spectre of famine and excessive population growth as a way to gain greater support for GM as a whole. But GM crops can only help to feed the world if attention is paid to the processes of technology development, to benefit-sharing, and to low-cost methods of production. Most commentators agree that food production will have to increase, and that this will have to come from existing farmland. But past approaches to modern agricultural development have not been successful in all parts of the world.

In most contexts, people are hungry because they are poor. They simply do not have the money to buy either the food they need or the modern technologies that could increase their yields. What they need are readily available and cheap means to improve their farm productivity. So a cereal crop engineered to have bacteria on the roots to fix free nitrogen from the air, or another with the apomixis trait, would be a great benefit for poor farmers. But unless such technologies are cheap, they are unlikely to be accessible to the very people who need them most.

As indicated earlier, agroecological approaches and agricultural sustainability are now an increasingly viable option for many farmers in developing and industrialized countries alike. But where there are no alternatives to specific problems, then GM could bring forth novel and effective options. If research is conducted by public-interest bodies, such as universities, non-government organizations and governments themselves, whose concern is to produce public goods, then biotechnology could result in the spread of technologies that have immense benefits.

Genetically modified organisms are not a single, homogeneous technology. Each application brings different potential benefits and risks for different stakeholders. Regulators, therefore, face special challenges in the face of rapidly developing technical applications. To date, the general approach to risk assessment in agriculture as a whole has been to establish rigorous procedures prior to release, but then to assume that farmers engage in 'good agricultural practice'. The novel nature of emerging policies centres on a fundamental shift in risk assessment to a need to understand the effects of technologies in the field and on the farm. Much of the harm to the environment arises when technologies, whether pesticides, fertilizers or machinery, are not used in accordance with regulators' criteria. The assessment of GMs will, however, now contain new requirements to assess the effects in the context of diverse farm practices, and how this interaction will affect desirable environmental outcomes, such as the integrity of local biodiversity. Such new risk assessments could have a positive side effect by increasing our understanding of agricultural–environment interactions in agricultural systems at large.

There are many types of application of biotechnology, and likely to be several distinct generations of released technologies. It would be wrong, therefore, to generalize about genetic modification – each application needs to be addressed on a case-by-case basis. We need to ask questions about who produces each technology and why; whether it can benefit the poorest, and if so how will they access it; and whether it will have adverse or positive environmental and health side effects. It is likely that biotechnology will make some contributions to agricultural sustainability, but developing the research systems, institutions and policies to make them pro-poor will be more difficult.

Policy Challenges

What we do not yet know is whether a transition to sustainable agriculture will result in enough food to meet the current food needs in developing and industrialized countries, let alone the future needs after continued population growth and the adoption of more urban and meat-rich diets. But what we are seeing is highly promising. There is also scope for additional confidence, as evidence indicates that productivity can grow over time if natural, social and human assets are accumulated.

Sustainable agriculture systems appear to become more productive when human capacity increases, particularly in the form of farmers' capacity to innovate and adapt their farm systems for sustainable outcomes. Sustainable agriculture is not a concretely defined set of technologies, nor is it a simple model or package to be widely applied or fixed with time. It needs to be conceived of as a process for social learning. Lack of information on agroecology and necessary skills to manage complex farms is a major barrier to the adoption of sustainable agriculture.

A problem is that we know much less about these resource-conserving technologies than we do about the use of external inputs in modernized systems. So it is clear that the process by which farmers learn about technology alternatives is crucial. If they are enforced or coerced, then they may only be adopted for a limited period. But if the process is participatory and enhances farmers' ecological literacy of their farms and resources, then the foundation for redesign and continuous innovation is laid.

The idea of agricultural sustainability, therefore, raises important policy questions. In particular, should farmers receive public support for the public benefits they produce in addition to food? Should those that pollute have to pay for restoring the environment and human health? These two principles are called 'the provider gets' and 'the polluter pays', and they are important to both industrialized and developing countries. Three categories of policy instruments are available: advisory and institutional measures, regulatory and legal measures and economic instruments. In practice, effective pollution control and supply of desired public goods requires a mix of all three approaches, together with integration across sectors (MEA, 2005).

Advisory and institutional measures have long formed the backbone of policies to internalize costs and so prevent agricultural pollution. These rely on the voluntary actions of farmers, and are favoured by policy makers because they are cheap and adaptable. Advice is commonly given in the form of codes of good agricultural practice, such as recommended rates of application of pesticides and fertilizer, or measures for soil erosion control. Most governments still employ extension agents to work with farmers on technology development and transfer. A variety of institutional mechanisms can also help to increase social capital and the uptake of more sustainable practices, including encouraging farmers to work together in study groups, investing in extension and advisory services to encourage greater interaction between farmers and extensionists, and encouraging new partnerships between farmers and other rural stakeholders, as regular exchanges and reciprocity increase trust and confidence, and lubricate cooperation.

Regulatory and legal measures are also used to internalize external costs. This can be done either by setting emissions standards for the discharge of a pollutant, or by establishing quality standards for the environment receiving the pollutant. Polluters who exceed standards are then subject to penalties. There are many types of standards, such as operating standards to protect workers, production standards to limit levels of contaminants of residues in foods, emissions standards to limit releases or discharges, such as silage effluents, and environmental quality standards for undesirable pollutants in vulnerable environments, such as pesticides in water. But the problem with such regulations is that most agricultural pollutants are diffuse, or non-point, in nature. It is impossible for inspectors to ensure compliance on hundreds of thousands of farms in the way that they can with a small number of factories. Regulations are also used to eliminate certain practices, and include bans on spraying of pesticides close to rivers and on straw-burning in the UK, and the mandatory requirement to complete full nutrient accounts for farms, such as in the Netherlands and Switzerland. A final use for regulations is the designation and legal protection of certain habitats and species, which are set at national or international levels.

Economic instruments can be used either to ensure that the polluter bears the costs of the pollution damage and the abatement costs incurred in controlling the pollution. They can also be used to reward good behaviour. A variety of economic instruments are available for achieving internalization, including environmental taxes and charges, tradable permits and the targeted use of public subsidies and incentives. Environmental taxes seek to shift the burden of taxation away from economic 'goods', such as labour, towards environmental 'bads', such as waste and pollution. Clearly the market prices for agricultural inputs do not currently reflect the full costs of their use. Environmental taxes or pollution payments, however, seek to internalize some of these costs, so encouraging individuals and businesses to use them more efficiently. Such taxes offer the opportunity of a 'double dividend' by cutting environmental damage, particularly from non-point sources of pollution, whilst promoting welfare. However, many opponents still believe that environmental taxes stifle economic growth.

There are now a wide range of environmental taxes used by countries in Europe and North America. These include carbon and energy taxes in Belgium, Denmark and Sweden; chlorofluorocarbon taxes in Denmark and the US; sulphur taxes in Denmark, France, Finland and Sweden; nitrogen oxide charges in France and Sweden; leaded and unleaded petrol differentials in all EU countries; landfill taxes in Denmark, the Netherlands and the UK; groundwater extraction charges in the Netherlands; and sewage charges in Spain and Sweden. However, environmental taxes have rarely been applied to agriculture, with the notable exception of pesticide taxes in Denmark, Finland, Sweden and in several states of the US; fertilizer taxes in Austria, Finland, Sweden and again several states of the US; and manure charges in Belgium and the Netherlands (Ekins, 1999).

The alternative to penalizing farmers through taxation is to encourage them to adopt non-polluting technologies and practices. This can be done by offering direct subsidies for adoption of sustainable technologies, and by removing perverse subsidies that currently encourage polluting activities. An important policy principle suggests that it is more efficient to promote practices that do not damage the environment rather than to spend on cleaning up after a problem has been created. Many governments provide some direct or indirect public support to their domestic agricultural and rural sectors. Increasingly, payments are being shifted away from being production linked, such as through price support or direct payments, to being retargeted to support sustainable practices. Generally, though, only small amounts of total budgets have been put aside for environmental improvements through such policies as the US Conservation Reserve Programme, the EU's agri-environmental and rural development programmes, and the Australian Landcare programme. Many now believe that all public support for farming should be entirely linked to the provision of public environmental and social goods and services.

The substantial external costs of modern agriculture, and the known external benefits of sustainable agricultural systems, pose great challenges for policy makers. A range of policy reforms could do much to internalize some of these costs and benefits in prices. In practice, as no single solution is likely to suffice, the key issue rests on how policy makers choose an appropriate mix of solutions, how these are integrated, and how farmers, consumers and other stakeholders are involved in the process of reform itself. Attention will therefore need to be paid to the social and institutional processes that both encourage farmers to work and learn together, and result in integrated cross-sectoral partnerships. Policy integration is vital, yet most policies seeking to link agriculture with more environmentally-sensitive management are still highly fragmented.

Agricultural Modernization and Interactions with Nature

Agriculture has had many 'revolutions' throughout history, from its advent some 8–10,000 years ago to the renowned 17th–19th-century agricultural revolution in Europe. In the past century, rural environments in most parts of the world have also undergone massive transformations. In some senses, these have been the most extraordinary in their speed of spread of new technologies and the far-reaching nature of their impacts upon social, economic and ecological systems.

Two guiding themes have dominated this period of agricultural and rural development. One has been the need for increased food production to meet the needs of growing populations. Governments have intervened to transform traditional agricultural systems by encouraging the adoption of modern varieties of crops and modern breeds of livestock, together with associated packages of external inputs (such as fertilizers, pesticides, antibiotics, credit, machinery) necessary to make these productive. In addition, they have supported new infrastructure, such as irrigation schemes, roads and markets, guaranteed prices and markets for agricultural produce, as well as a range of other policies. The other theme has been the desire to prevent the degradation of natural resources, perceived to be largely caused by growing populations and their bad practices. To conserve natural resources, governments have encouraged the adoption of soil and water conservation measures to control soil erosion. They have established grazing management schemes to control rangeland degradation. They have excluded people from forests and other sites of high biodiversity to protect wildlife and plants.

According to just these two themes, it would appear that agricultural and rural development has been remarkably successful. Both food production and the amount of land conserved have increased dramatically. Although often seen as mutually exclusive, both have been achieved with largely the same process of modernization. The approach is firmly rooted in and driven by the enlightenment tradition of positivist science (Harvey, 1989; Kurokawa, 1991). External actors identify the problem that needs solving, in these cases too little food or too much degradation. Their concern is to intervene so as to encourage rural people to change their practices. Rational solutions are proposed, and technologies developed. These technologies, known to work in a research station or other controlled environments, are assumed to work elsewhere. They are then passed to the mass of rural people and farmers, and the benefits awaited.

It was Cartesian reductionism and the enlightenment that set the scene for this approach, largely casting aside the assumed folklore and superstitions of age-old thinking. A revolution in science occurred in the late 16th and 17th centuries, largely due to the observations, theories and experiments of Bacon, Galileo, Descartes and Newton, which brought forth mechanistic reductionism, experimental inquiry and positivist science. These methods brought great progress, and continue to be enormously important. But one unfortunate side effect has been an enduring separation of humans from the rest of nature. In the 19th and 20th centuries, wilderness writers, landscape painters, ecologists and farmers sought to reverse, or at least temper, the dominance of this new thinking. It is, though, in the indigenous groups of the world that we find surviving examples of close nature–people connectivity. One of the most comprehensive collections on the diversity of human cultures and their connectedness with nature and the land is Darrell Posey's *Cultural and Spiritual Values of Biodiversity* (1999). Containing contributions from nearly three hundred authors from across the world, these highlight 'the central importance of cultural and spiritual values in an appreciation and preservation of all life'. These voices of the earth demonstrate the widespread intimate connectivity that people have with nature, whether as hunter-gatherers or agriculturalists.

Johan Mathis Turi of the Saami reflects on the mutual shaping in the Norwegian arctic: 'The reindeer is the centre of nature as a whole and I feel I hunt whatever nature gives. Our lives have remained around the reindeer and this is how we have managed the new times so well. It is difficult for me to pick out specific details or particular incidences as explanations for what has happened because my daily life, my nature, is so comprehensive. It includes everything. We say "lotwantua", which means everything is included.' A similar perspective is put by Gamaillie Kilukishah, an Inuit from northern Canada who in translation by Meeka Mike says, 'You must be in constant contact with the land and the animals and the plants... When Gamaillie was growing up, he was taught to respect animals in such a way as to survive from them. At the same time, he was taught to treat them as kindly as you would another fellow person.'

Pera of the Bakalaharil tribe in Botswana points to their attitudes in using and sustaining wild resources: 'Some of our food is from the wild – like fruits and some of our meat... We are happy to conserve, but some conservationists come and say that preservation means that we cannot use the animals at all. To us, preservation means to use, but with love, so that you can use again tomorrow and the following year.' Says Cristina Gualinga of the Quicha, 'Nature, what you call biodiversity, is the primary thing that is in the jungle, in the river, everywhere. It is part of human life. Nature helps us to be free, but if we trouble it, nature becomes angry. All living things are equal parts of nature and we have to care for each other.' Finally, in

Australia, Henrietta Fourmile of the Polidingi Tribe says: 'Not only is it the land and soil that forms our connections with the earth but also our entire life-cycle touches most of our surroundings. The fact that our people hunt and gather these particular species on the land means emphasis is placed on maintaining their presence in the future... What is sometimes called "wildlife" in Australia isn't wild; rather it's something that we have always maintained' (all quotes in Posey, 1999).

Part 1: Before Agriculture

For almost all of human history, people have been hunter-gatherers. If, as seems likely, hominids emerged around 6 million years ago, then some 300,000 generations passed before agriculture was invented, since when some 500–600 generations passed until the emergence of the industrialized era. We must have been good at hunting and gathering, otherwise hominids would never have made it to the present day. Yet in recent times, hunter-gatherer societies have been characterized as backward, uncivilized and unable to enter the modern world. After Darwin, the concept of evolution as a linear and progressive force became widely adopted, and remains with us today. Jean Lamarck erroneously believed in the inheritance of acquired characteristics, and he suggested that species strove to evolve greater complexity, and thus the pinnacle of evolution had to be humans.

Later, Social Darwinism came to suggest that nature was more important than nurture, and that the development of individuals from birth to death (ontogeny) reflected closely the evolutionary development of species (phylogeny). Such ideas of progression (implying that the later is better, and the more complex the cleverer), were subsequently applied to human societies. Lewis Henry Morgan's *Ancient Society*, published in 1877, suggested seven stages of human cultural evolution, beginning with lower savagery and progressing through barbarism eventually to reach civilization. The idea was that all human societies did share a common ancestor, but that some groups (or races) were now higher on the ladder than others. Such ideas fitted very well with prevailing views about the superiority of European and North American culture, and again came to be widely accepted (though of course still hotly contested by many). It was not until the later 20th century that new perspectives began to emerge.

Richard Lee was one of the pioneers of the later 20th century who clearly demonstrated the efficiencies and effectiveness of hunter-gatherer lifestyles. This first paper is drawn from the classic *Man the Hunter* (1968), and shows how hunter-gatherers do not have a precarious existence in which they struggle to survive – the view that had become common. The hunter-gatherer resource base is 'at least routine and reliable and at best surprisingly abundant'. The chapter draws particularly on evidence from the !Kung Bushmen of the Kalahari Desert, and illustrates in detail the wide range of food resources used by local people in this extremely challenging environment. A key finding (again, counter-intuitive to many at the time) was that hunter-gatherers have plenty of time for leisure, often working fewer hours than agriculturalists, and the caloric returns of their activities are good.

Richard Lee and Richard Daly's later *Cambridge Encyclopedia of Hunters and Gatherers* (1999) is an important and comprehensive volume containing case studies of more than 50 of the world's remaining hunter and gatherer peoples. These tell a story of resilience in the face of change, and of the many ways they are affected by modern problems. Thematic essays discuss prehistory, social life, gender, music and art, food and health, religion and indigenous knowledge. In their introductory essay, Lee and Daly make the point that the world's hunter-gatherer peoples – the Arctic Inuit, Aboriginal Australians, Kalahari San and other similar groups – represent the oldest and perhaps most successful human adaptation. Until 12,000 years ago, virtually all humanity lived as hunters and gatherers. Yet in recent centuries they have suffered the ill-effects of modernity. However, fascination with hunting peoples and their ways of life still remains strong. Hunters and gatherers stand at the opposite pole from the dense urban life now experienced by a large proportion of humanity. Yet these same hunters may hold the key to many contemporary concerns – about diet, politics, communities, physical activity and relations with nature. A late Australian Aboriginal writer is quoted here, 'modern ecology can learn a great deal from a people who managed and maintained their world so well for 50,000 years'.

The third paper in this section is from Hugh Brodie's *The Other Side of Eden* (2000). His fieldwork experience is mainly from the polar and boreal north, and he weaves the experiences of native hunter-gatherers into a narrative that reveals a paradox: agriculture is a settled activity, yet has been fundamentally expansionist; whereas hunter-gathering is a mobile activity, cultures and communities self-regulate and stay in the same areas over thousands of years. This points to a problem – current narratives often describe hunter-gatherers as the backward and irresponsible peoples, yet left alone they do not seek to impinge on others. This chapter, entitled *Mind*, explores some of the differences between communities, and shows how change has often been destructive to whole hunter-gatherer peoples. Says Mary Adele, an Innu of Labrador, 'on the land, we are ourselves. In the settlements we are lost.That was why they made our minds weak'. Some believe that hunter-gatherers will inevitably become extinct; others that they represent ways of living that are instructive. Says Brodie, 'without hunter-gatherers, humanity is diminished and cursed; with them, we can achieve a more complete version of ourselves'.

The fourth chapter of this opening section focuses on the Innu of northern Labrador, and analyses the environmental and health benefits of hunting lifestyles and diets. They have undergone profound transitions in recent decades with important implications for conservation, food and health policy. The change from permanent nomadic hunting, gathering and trapping in the country (*nutshimit*) to sedentary village life (known as 'sedentarization') has been associated with a marked decline in physical and mental health. The overarching response of the national government has been to emphasize village-based and institutional solutions. Samson and Pretty show that changing the balance back to country-based activities would address both the primary causes of the crisis and improve the health and well-being of the Innu. Drawing on ethnographic fieldwork, interviews with Innu older people (*Tshenut*), empirical data on nutrition and activity, and comparative data from the experiences of other indigenous peoples, they identify biological and environmental transitions of significance to the current plight of the Innu.

They also show that nutrition and physical activity transitions have had major negative impacts on individual and community health. However, hunting and its associated social and cultural forms is still a viable option as part of a mixed livelihood and economy in the environmentally significant boreal forests and tundra of northern Labrador. Cultural continuity through Innu hunting activities is a means to decelerate, and possibly reverse, their decline. Finally, four new policy areas to help restore country-based activities are suggested: (i) a food policy for country food; (ii) an outpost programme; (iii) ecotourism; and (iv) an amended school calendar.

In the final paper of this section, Luisa Maffi analyses the concept of biocultural diversity and how it relates to current concerns about both ecological and cultural sustainability. Biocultural diversity draws on anthropological, ethnobiological and ethnoecological insights about the relationships between human language, knowledge and practices with the environment. Evidence now indicates that the idea of the existence of pristine environments unaffected by humans is erroneous. Humans have maintained, enhanced and even created biodiversity through culturally diverse practices over many thousands of generations. There are some suggestions that biodiversity and cultural diversity in the form of linguistic differences are associated, though at the local level these relationships do not always stand up to scrutiny. But the role of language is nonetheless critical as a vehicle for communicating and transmitting cultural values, traditional knowledges and practices, and thus for mediating human–environment interactions.

Landscapes can be networks of knowledge and wisdom, conveyed by the language of local people. But the problem is that many languages are under threat. There are some 5000–7000 languages spoken today, of which 32 per cent are in Asia, 30 per cent in Africa, 19 per cent in the Pacific, 15 per cent in the Americas, and 3 per cent in Europe. Yet only half of these languages are each spoken by more than 10,000 speakers. Some 90 per cent of all the world's languages may disappear in the course of this century – yet these very languages are tied to the creation, transmission and perpetuation of local knowledge and cultural behaviour. As language disappears, so does people's ability to understand and talk about their worlds. Natural and cultural continuity are thus connected. The phenomenon of loss has been called the extinction of experience – and the loss of traditional languages and cultures may be hastened by environmental degradation.

Yet in many parts of the world, both in developing and industrialized countries, such traditional ecological knowledge is declining and under threat of extinction. As humans coevolved with their local environments, and have now come to be disconnected, so knowledges that coded stories, binding people to place, have become less valued. New efforts to analyse biocultural diversity on a country-by-country basis are reviewed, and despite some important progress in the international sphere, such as in the Convention on Biodiversity, the most fundamental changes must come from ground-up actions.

Part 2: Early Agriculture

Some 10,000 years ago, hunter-gatherers in various parts of the world began to domesticate some wild plants and animals. These evolved over thousands of seasons under the guidance of people, producing domesticated forms strikingly different from their wild progenitors. Now, wheat, rice, maize, sorghum, barley, potato, cassava, taro, yam, sweet potato and grain legumes are the main sources of human nutrition for billions of people. Plant geneticist, Jack Harlan, reflects on these processes that generated huge reserves of genetic diversity, pointing to the importance of the intimate knowledge of crops by so-called primitive agricultural societies. Centres of diversity are found on every continent (except Australia, where native people did not widely domesticate plants). These centres are characterized by ancient agriculture, great ecological diversity and great human diversity. Such centres were first recognized and described by the Russian agronomist N I Vavilov. This paper goes on to describe contemporary efforts to protect crop genetic diversity in the face of modernizing tendencies to simplify agriculture.

All agricultural systems need water. A few can rely only on rainfall, but most require some kind of system to manage the collection and delivery of water to crops and livestock. Karl Wittfogel's classic *Oriental Despotism* explored the characteristics of hydraulic economies: they involve a division of labour; they intensify cultivation; and they necessitate cooperation on a large scale. All three contribute to the requirement for a particular type of management of both inputs, including water, and outputs of food to markets and consumers. Water necessitates control, and some of this has to be very large-scale, both for flood protection (such as in Egypt or Mesopotamia) and for irrigation management (such as for the rice terrace cultures of Asia). Cooperation is also essential, as water can be captured by the more powerful, and tail-enders in irrigation systems can easily go without. Wittfogel's contribution is to show how such cooperation easily slips into coercion, with punishment for transgression never really absent. Agrohydraulic societies also require active timekeeping and calendar-making and close observation of weather, seasonal patterns and astronomy, as well as the capacity to build canals, dams, roads and other monuments.

Marcus Porcius Cato lived 234–149 BC, and was known as the Orator, the Censor or Cato Major. He was born at Tusculum, some 15km from Rome. His youth was spent on his father's farm, and a love for the soil remained with him though life. He entered the military aged 17 and served in the Second Punic War. Political offices came later, including the consulship in 195 and the censorship in

184 BC. He was always the champion of the common people. Quintilian speaks of Cato's great versatility as a general, philosopher, orator, historian and expert on agriculture. *De Agri Cultura* resembles a farmer's notebook, and constitutes the earliest surviving specimen of connected prose. Although haphazard in style, it contains many long-standing truths, including on the first page, 'And when they would praise a worthy man, their praise took this form: good husbandman, good farmer; one so praised was thought to have received the greatest commendation'.

Marcus Terentius Varro was born more than 30 years after Cato's death, and lived 116–27 BC. He was born in Reate, where Cato's father had his farm, and devoted his life to literature and the antiquities. Under the political banner of Pompey, he held the offices of tribune, aedile and praetor. He came into conflict with Caesar for twice supporting Pompey, was later forgiven and then commanded by Caesar to supervise the great library. Varro claimed by his 78th year to have written several hundred books, but only six survive. The *Res Rusticae* was begun in Varro's 80th year, and it contains perhaps the earliest suggestion of the importance of sustainability in farming. Identified first by Gordon Conway, a section in Varro's third book states that 'agriculture is not only an art, but an important and noble art. It is, as well, a science, which teaches what crops are planted in each kind of soil … in order that the land may regularly produce the largest crops (quo terra maximos perpetuo reddat fructus)'.

Li Wenhua provides an historical review of the emergence of agroecological farming systems in China. As he says, 'for thousands of years, Chinese philosophers have pondered on the harmonious relationship between humans, nature and the environment'. As a result, many effective technologies and practices have been developed (and also forgotten), some of which are now being championed today. It is in China that there is the greatest and most continuous record of agriculture's development. He dates the earliest records of integrated crop, tree, livestock and fish farming to the Shang-West Zhou Dynasties of 1600–800 BC. Later Mensius said in 400 BC, 'if a family owns a certain piece of land with mulberry trees around it, a house for breeding silkworms, domesticated animals raised in its yard for meat, and crop fields cultivated and managed properly for cereals, it will be prosperous and will not suffer starvation'. In one of the earliest recognitions of the need for the sustainable use of natural resources, he also said, 'if the forests are timely felled, then an abundant supply of timber and firewood is ensured, if the fishing net with relatively big holes is timely cast into the pond, then there will be no shortage of fish and turtle for use'.

Still later, other treatises such as the collectively written *Li Shi Chun Qiu* (239 BC) and the *Qi Min Yao Shu* by Jia Sixia (600 AD) celebrated the fundamental value of agriculture to communities and economies, and documented the best approaches for sustaining food production without damage to the environment. These included rotation methods and green manures for soil fertility, the rules and norms for collective management of resources, the raising of fish in rice fields, and the use of manures. Li Wenhua indicates that, 'these present a picture of a prosperous, diversified rural economy and a vivid sketch of pastoral peace'. The chapter goes on to describe the emergence of modern integrated farming systems, including the innovative eco-county programme promoted by the Chinese government from 1994 onwards. Ecological agriculture, with a long history of development in ancient China, is now being 'enriched and upgraded with the progress of modern science and technology, and has gradually become a real approach for sustainable agriculture'.

In 1911, F H King's *Farmers of Forty Centuries* was first published, showing for the first time to the Western world many of the details of agricultural practices and customs of China, Korea and Japan. At that time, the US was 'as yet a nation of but few people widely scattered over a broad land', and yet the ancient cultures of the Far East had been intensively farming for several thousand years on the same land. Here, then, is an early indication of the importance and relevance of sustainability, not that King used this term. Sustainability at least implies being able to do the same thing over long periods of time without causing harm to the environment, and King in his travels came to realize this was precisely what farmers in these three countries had been doing for at least 40 centuries. Many factors were important, including careful selection of crops and livestock breeds, water management and soil fertility maintenance. Manures from both animals and humans were widely used, soil amendments of canal mud regularly dredged and applied to fields, and nitrogen-fixing legumes were widespread in a variety of rotation patterns. King indicates, 'almost every foot of land is made to contribute material for food, fuel or fabric'.

Part 3: Agricultural Revolutions and Change

The landscape itself is a type of common property. It can be enjoyed and appreciated by many if, of course, they are allowed to access it. The idea of commons implies jointness, something people can enjoy either collectively or individually and from which they derive value. Over the centuries, two types of common management emerged in Europe. These were for the common or open-field system of cropland, which persisted for a thousand years, and the common management of wild resources, woodlands, pastures, wastes, rivers and coasts. In these systems, local people held rights for grazing, cutting peat for fuel (turbaries), cutting timber for housing (estovers), grazing acorns and beech mast (pannage), and fishing (piscary).

Over the years, though, both types of common came to be steadily enclosed and privatized, mostly as a result of the actions of landowners and the state driven by the prevailing view that commons were inefficient. The result was an extraordinary transformation of the landscape, particularly in the 18th and early 19th centuries. In the UK, local enclosure had been occurring up to the 17th century, but the process accelerated with the introduction of parliamentary inclosure acts, dating from the early 18th century and continuing through 2750 Acts to 1845, the date of the last general Inclosure Act. At the same time, wastes, heaths, moors and commons were enclosed through 1800 Acts between 1760 and the 1840s. Commissioners with extensive powers were appointed to redesign the landscape in more than 3000 parishes. As a result, 2.75 million hectares of common land were enclosed, comprising 1.82 million hectares of open-field arable, and 0.93 million hectares of so-called wastes. To put this in perspective, there are about 18 million hectares of agricultural land in the UK, of which just 4 million are currently under arable farming, and about half a million still under common land.

In the first paper of this section, Michael Turner and colleagues analyse open-field agriculture of 17th and 18th century England, and show how collective community action had developed to protect scarce resources, and how pressure upon these resources through changing economic and demographic conditions inspired communities to develop and promote sustainable methods of husbandry and management. They show how ecological integrity and equitable ownership in decision making went hand-in-hand. This is in stark contrast to the dominant narrative of the time – that the commons were inefficient and backward.

The next paper describes the elements of the agricultural change in 17th–18th-century Europe in what has generally come to be called *The* Agricultural Revolution. During a period where there was no government ministry of agriculture, no national agricultural research or extension agencies, no radio or TV, no pesticides or inorganic fertilizers, and poor rural transport infrastructure, aggregate cereal and livestock production increased to unprecedented levels. In the 150 years after 1700, wheat production in Britain increase four-fold, and barley and oats three-fold; the number of cattle supplied to markets tripled and sheep doubled. Two components were vital: a wide range of innovative technologies were developed by farmers, and then these were spread to other farmers through tours, farmer groups, open days and publications, and then adapted to local conditions by rigorous experimentation. New crops offered diversification opportunities to farmers by allowing intensification of land use. Increased fodder supply meant more livestock, and so increased the supply of manure to improve soil fertility. Selective breeding of livestock produced more efficient conversion of feed to meat, so permitting slaughter at an earlier age and higher stocking rates. New labour-saving machinery released farmers from labour-bottlenecks at cereal and hay harvests, and new tools and techniques improved the efficiency of seed saving. Farmers widely experimented with livestock breeding, irrigation, drainage, handtools and pest control.

The Green Revolution of the latter half of the 20th century was another significant agricultural revolution. Without it, poverty and hunger would be much more widespread, especially as it coincided with a period of rapid worldwide population growth. In this chapter, drawn from Gordon Conway's *Doubly Green Revolution*, the factors of success of the green revolution are discussed and analysed. Fundamental to success was the application of modern science and technology to the task of getting crops to yield more. The success of the green revolution lay in its simplicity. Agricultural scientists bred new varieties of staple cereals that matured quickly, so permitting two or three crops to be grown each year; that were day-length insensitive, so could be extended to farmers at a wide range of latitudes; and that were producers of more grain at the expense of straw. They were also much more nitrogen-responsive than traditional varieties. These modern varieties were distributed to farmers together with inputs, including inorganic fertilizers, pesticides, machinery, credit and water regulation. These technical innovations were then implemented in the best favoured agroclimatic regions and for those classes of farmers with the best expectations of and means for realizing the potential yield increases.

Conway draws attention to the limitations of the green revolution – its impact on the poor has been less than expected, it has not reduced natural resource degradation, its geographic impact has been localized, and there are signs of diminishing returns. In particular, the green revolution missed many agricultural systems which, until recently, represent a largely forgotten agriculture. These tend to be located in the drylands, wetlands, uplands, savannas, swamps, near-deserts, mountains and hills, and forests. Farming systems in these areas are complex and diverse, agricultural yields are low, and rural livelihoods are often dependent on wild resources as well as agricultural produce. They are remote from markets and infrastructure; they are located on fragile or problem soils; and less likely to be visited by agricultural scientists and extension workers or studied in research institutions. The poorest countries tend to have higher proportions of these agricultural systems.

James Scott's book *Seeing Like a State* deploys the Greek term *mētis* to describe 'forms of knowledge embedded in local experience'. Mētis is normally translated as meaning 'cunning' or 'cunning intelligence', but Scott says this fails to do justice to a range of practical skills and acquired intelligence represented by the term. He contrasts such mētis with the 'more general, abstract knowledge displayed by the state and its technical agencies' by describing villagization in Tanzania and Ethiopia, Soviet collectivization, the emergence of high-modernist cities and the widespread standardization of agriculture. Failures come when mētis is designed out, as the state rarely makes the kinds of necessary daily adjustments required for the effective working of systems. Mētis, he says, is 'plastic, local and divergent... It is in fact the idiosyncrasies of mētis, its contextualities, and its fragmentation that make it so permeable, so open to new ideas'.

This particular chapter explores the Soviet collectivization project, and shows how high modernism was implemented by thinking big. Nearly everything was planned on a monumental scale – from cities, buildings, construction projects and collectivization of agriculture through rationalization and industrialization. Many of these ideas were imported from the US by Russian agronomists and engineers in the 1920s and 1930s. Some of the resulting projects were enormous. One Sovkhoz collective farm established 1600km south of Moscow cropped 150,000 hectares of solely wheat culture – and was later found to be an abject failure. The state prosecuted a 'war' against the peasantry in the period of 1930–1934 in order to liquidate the kulaks (peasant farmers) and enforce collectivization. The ensuing famine resulted in a death toll of at least 3–4 million people, and possibly as many as 20 million.

In the final chapter of this section, Pedro Sanchez and colleagues set out the themes and challenges for alternatives to slash-and-burn agriculture. Known also as shifting, swidden, milpa, shamba, jhum and kaingin agriculture, slash-and-burn has long been a sustainable and persistent form of agricultural system in the forests of the tropics and sub-tropics. Trees are cleared, crops grown for 1–2 years, livestock then grazed, and then the community moves to cut another area of the forest. Provided they do not return for 20–30 years to the same plot, then sufficient time elapses for the forest fully to regenerate, and the system can persist over long periods. But when total forest cover declines, through logging, ranching or other development projects, or population increases, then the rotation cycle shortens, and the system cannot retain its fertility and success. In some quarters, small farmers engaged in slash-and-burn are blamed for the destruction of tropical rainforests, but in truth it is other pressures that have made their management systems no longer viable. This chapter documents the recent international efforts to produce effective alternatives to slash and burn for the roughly 40 million people (2 per cent of the world's agricultural population in the tropics) of Latin America, Africa and Asia who currently rely on these systems of management. Lands can be rehabilitated with the right scientific and technological innovations, as well as the appropriate social, economic and policy support.

Part 4: Modern Agricultural Reforms

The knowledge that soil erosion was both costly and damaging was first appreciated on a wide scale by agricultural authorities in the US and colonial Africa and India in the early part of the 20th century. They took the view that farmers were mismanagers of soil and water, and so had to be encouraged to adopt conserving practices. Erosion was considered a technical problem requiring only technical action, and so authorities encouraged farmers to construct terraces, bunds (embankments of soil), ditches and drains, and to adopt alternative cropping patterns and contour planting. They also resettled people to discourage the use of certain lands, and destocked other regions of livestock to reduce grazing pressure.

The first chapter in this section by Pretty and Shah describes how this style of intervention was first established in the US. It emerged followed the period of severe wind erosion and dust storms that came to be known as the Dust Bowl of the early 1930s. Even though there were subsidies to encourage farmers to adopt new measures, authorities were granted wide-ranging powers to enforce land use regulations. This pattern of intervention was then repeated by colonial authorities in Africa and Asia. Early regulations had been adapted to local conditions and were grounded in farming and grazing practice. But later, administrators travelling to the US saw the devastation, and brought back recommendations for large-scale bunding and ridging, combined with contour ploughing and planting. Locally adapted practices were largely ignored, even though they were more effective in droughts. These measures were imposed on farmers, who were then monitored closely to ensure their compliance. In some countries, this meant the compulsory resettlement of many people to new villages.

This has been the style for many soil conservation programmes. Technologies known to work under certain conditions are widely used or recommended, and backed up by local and national policies that give powers to the state to execute specified improvements on farmers' fields and to allocate the costs of these improvements between the farmers and the state. In many places, provisions have been made for compulsory treatment of the fields of farmers refusing land treatment. This has led to increased alienation with, for example, people uprooting plantations and destroying fencing and conservation measures. The quantitative achievements of conventional soil conservation programmes can appear impressive. Throughout the world, terraces have been built, trees planted and farmers trained on a massive scale. Yet these results have often been short-lived, tending to occur only within project boundaries and before project completion. If performance is measured over long periods, the results have been extraordinarily poor for the amount of effort and money expended: technologies have neither persisted nor spread independently into non-project areas.

In the second paper, Erick Fernandes and colleagues summarize the types of transitions effected by the Green Revolution, and then set out a vision for agriculture centred on field-culture, with sensitivities towards patterns in space and time. Monocultures are often erroneously seen as real agriculture, yet it is polycultures that have long offered rural people opportunities to maintain on-farm diversity of products and their functions. Multifunctional systems with many components are more resilient and meet many needs compared with mono-functional systems. This chapter sets out four ideas that need revising: that pest control always needs pesticides, that soil fertility constraints always need chemical fertilizers, that solving water problems needs new irrigation, and that raising productivity only needs genetic and breeding approaches. There are many productive opportunities that can arise by adopting more biological and people-centred approaches to agricultural development and its sustainability.

The third paper is the second of two chapters from Li Wenhua's 2001 book on agroecological farming systems in China. This long chapter contains considerable detail on integrated farming systems at different scales from homestead gardens, eco-villages, eco-counties and forest shelterbelts. All contain many significant innovations of relevance to many systems elsewhere in the world. Most rural families in China have very small amounts of land, on average 0.02ha per household, and so their approaches need to be intensive, make effective use of all resources, and above all produce enough food. Of particular importance are the sections on eco-villages and eco-counties. Both represent geographically integrated efforts of what is called ecological engineering in China.

The benefits of integrated systems for local people and the environment can be substantial – more income from the vegetables, better and more diverse food, reduced costs for fertilizers, reduced workload for women, and better living conditions in the house and kitchen. The Ministry promotes a variety of integrated models across the country, involving mixtures of biogas digesters, fruit and vegetable gardens, underground water tanks, solar greenhouses, solar stoves and heaters, and pigs and poultry. These are fitted to local conditions. Whole integrated systems are now being demonstrated across many regions of China, and altogether 8.5 million households have biogas digesters. The target for the coming decade is the construction of another one million digesters per year. As the systems of waste digestion and energy production are substituting for fuelwood, coal or inefficient crop-residue burning, the benefits for the natural environment are substantial – each digester saves the equivalent of 1.5 tonnes of wood per year, or 3–5mu of forest. Each year, these biogas digesters are effectively preventing 6–7 million tonnes of carbon from being emitted to the atmosphere.

Biotechnology remains a controversial topic in agricultural development. Some believe it represents huge risks to agricultural and natural systems; others indicate that such new technologies are essential for agricultural development. Neither view is entirely correct, as biotechnology, and particularly genetic modification, is not one thing, but a wide variety of technologies that represent different potential benefits and risks. Thus assessment should be on a case-by-case basis so that useful technologies are able to be used by farmers, and potentially harmful ones not approved for cultivation. In this paper, Doreen Mnyulwa and Julius Mugwagwa review agricultural biotechnology and its safety mechanisms across southern Africa. Only in South Africa itself have GM crops been commercially cultivated to date, and these are already proving beneficial to small farmers. Some of these technologies have been developed within South Africa with domestic government support. Yet the murky interface between food aid, international politics, science and regulations remains complex, particularly over the potential 'dumping' of GM food aid to the region.

The final chapter of this volume is drawn from Michael Bell's excellent account of the transformations brought about by the Practical Farmers of Iowa (PFI). Formed to develop and spread new ideas for sustainable farming, this organization is run by farmers for themselves. They saw that big agriculture was no longer the success it made itself out to be, and realized they needed to help themselves by developing new ways of collaborating and generating new effective farming methods. But PFI is about much more than that. Bell begins by recalling a conversation with Dick Thompson, who has more than 20 years of innovation on his farm. Thompson says you should 'get along, but don't go along'. Get along by working with others, emphasizing the importance of communication and dialogue. Don't go along by not just following what others do – then adapt, change, evolve and be in control. This suggests a very different model for post- or non-modern agriculture. Not the land of monocultures and monologues, of simple diffusion of ideas and adoption of without thinking. Here is an approach to cultivation that embraces the creativity of difference and openness, a project that will never be finished. As Bell says, 'let us put the culture back in agriculture of all farms and all places'.

What Hunters Do for a Living, or, How to Make Out on Scarce Resources

Richard B. Lee

The current anthropological view of hunter-gatherer subsistence rests on two questionable assumptions. First is the notion that these peoples are primarily dependent on the hunting of game animals, and second is the assumption that their way of life is generally a precarious and arduous struggle for existence.

Recent data on living hunter-gatherers (Meggitt, 1964b; Service, 1960) show a radically different picture. We have learned that in many societies, plant and marine resources are far more important than are game animals in the diet. More important, it is becoming clear that, with a few conspicuous exceptions, the hunter-gatherer subsistence base is at least routine and reliable and at best surprisingly abundant. Anthropologists have consistently tended to under-estimate the viability of even those 'marginal isolates' of hunting peoples that have been available to ethnographers.

The purpose of this paper is to analyse the food getting activities of one such 'marginal' people, the !Kung Bushmen of the Kalahari Desert. Three related questions are posed: How do the Bushmen make a living? How easy or difficult is it for them to do this? What kinds of evidence are necessary to measure and evaluate the precariousness or security of a way of life? And after the relevant data are presented, two further questions are asked: What makes this security of life possible? To what extent are the Bushmen typical of hunter-gatherers in general?

Bushman Subsistence

The !Kung Bushmen of Botswana are an apt case for analysis.[1] They inhabit the semi-arid north-west region of the Kalahari Desert. With only six to nine inches of

Lee R B. 1968. What hunters do for a living, or, how to make out on scarce resources. In Lee R and Devore E. *Man the Hunter.* Aldine, Chicago, 30–48.

rainfall per year, this is, by any account, a marginal environment for human habitation. In fact, it is precisely the unattractiveness of their homeland that has kept the !Kung isolated from extensive contact with their agricultural and pastoral neighbours.

Fieldwork was carried out in the Dobe area, a line of eight permanent waterholes near the South-West Africa border and 125 miles south of the Okavango River. The population of the Dobe area consists of 466 Bushmen, including 379 permanent residents living in independent camps or associated with Bantu cattle posts, as well as 87 seasonal visitors. The Bushmen share the area with some 340 Bantu pastoralists largely of the Herero and Tswana tribes. The ethnographic present refers to the period of fieldwork: October 1963–January, 1965.

The Bushmen living in independent camps lack firearms, livestock and agriculture. Apart from occasional visits to the Herero for milk, these !Kung are entirely dependent upon hunting and gathering for their subsistence. Politically they are under the nominal authority of the Tswana headman, although they pay no taxes and receive very few government services. European presence amounts to one overnight government patrol every six to eight weeks. Although Dobe-area !Kung have had some contact with outsiders since the 1880s, the majority of them continue to hunt and gather because there is no viable alternative locally available to them.[2]

Each of the 14 independent camps is associated with one of the permanent waterholes. During the dry season (May–October) the entire population is clustered around these wells. Table 1.1 shows the numbers at each well at the end of the 1964 dry season. Two wells had no camp resident and one large well supported five camps. The number of camps at each well and the size of each camp changed frequently during the course of the year. The 'camp' is an open aggregate of cooperating persons which changes in size and composition from day to day. Therefore, I have avoided the term 'band' in describing the !Kung Bushman living groups.[3]

Table 1.1 *Number and distribution of resident Bushmen and Bantu by waterhole*[a]

Name of waterhole	*No. of camps*	*Population of camps*	*Other Bushmen*	*Total Bushmen*	*Bantu*
Dobe	2	37	—	37	—

!xabe	—	—	8	8	12
Mahopa	—	—	23	23	73
Total	14	248	88	336	340

Note: [a] Figures do not include 130 Bushmen outside area on the date of census.

Each waterhole has a hinterland lying within a six-mile radius which is regularly exploited for vegetable and animal foods. These areas are not territories in the zoological sense, since they are not defended against outsiders. Rather they constitute the resources that lie within a convenient walking distance of a waterhole. The camp is a self-sufficient subsistence unit. The members move out each day to hunt and gather, and return in the evening to pool the collected foods in such a way that every person present receives an equitable share. Trade in foodstuffs between camps is minimal; personnel do move freely from camp to camp, however. The net effect is of a population constantly in motion. On the average, an individual spends a third of his time living only with close relatives, a third visiting other camps, and a third entertaining visitors from other camps.

Because of the strong emphasis on sharing, and the frequency of movement, surplus accumulation of storable plant foods and dried meat is kept to a minimum. There is rarely more than two or three days' supply of food on hand in a camp at any time. The result of this lack of surplus is that a constant subsistence effort must be maintained throughout the year. Unlike agriculturalists who work hard during the planting and harvesting seasons and undergo 'seasonal unemployment' for several months, the Bushmen hunter-gatherers collect food every third or fourth day throughout the year.

Vegetable foods comprise from 60–80 per cent of the total diet by weight, and collecting involves two or three days of work per woman per week. The men also collect plants and small animals but their major contribution to the diet is the hunting of medium and large game. The men are conscientious but not particularly successful hunters; although men's and women's work input is roughly equivalent in terms of man-day of effort, the women provide two to three times as much food by weight as the men.

Table 1.2 summarizes the seasonal activity cycle observed among the Dobe-area !Kung in 1964. For the greater part of the year, food is locally abundant and easily collected. It is only during the end of the dry season in September and October, when desirable foods have been eaten out in the immediate vicinity of the waterholes that the people have to plan longer hikes of 10–15 miles and carry their own water to those areas where the mongongo nut is still available. The important point is that food is a constant, but distance required to reach food is a variable; it is short in the summer, fall and early winter, and reaches its maximum in the spring.

This analysis attempts to provide quantitative measures of subsistence status including data on the following topics: abundance and variety of resources, diet selectivity, range size and population density, the composition of the work force, the ratio of work to leisure time, and the caloric and protein levels in the diet. The value of quantitative data is that they can be used comparatively and also may be useful in archaeological reconstruction. In addition, one can avoid the pitfalls of subjective and qualitative impressions; for example, statements about food 'anxiety' have proven to be difficult to generalize across cultures (see Holmberg, 1950; and Needham's critique, 1954).

Table 1.2 *The Bushman annual round*

Season		*Jan.*	*Feb.*	*Mar.*	*April*	*May*	*June*	*July*	*Aug.*	*Sept.*	*Oct.*	*Nov.*	*Dec.*
			Summer Rains		*Autumn Dry*			*Winter Dry*			*Spring Dry*	*First Rains*	
Availability of water		Temporary summer pools everywhere			Large summer pools			Permanent waterholes only				Summer pools developing	
Group moves		Widely dispersed at summer pools			At large summer pools			All population restricted to permanent waterholes				Moving out to summer pools	
Men's subsistence activities	1.	Hunting with bow, arrows and dogs (Year-round)											
	2.	Running down immatures					Trapping small game in snares					Running down newborn animals	
	3.	Some gathering (Year-round)											
Women's subsistence activities	1.	Gathering of mongongo nuts (Year-round)											
	2.	Fruits, berries, melons					Roots, bulbs, resins				Roots, leafy, greens		
Ritual activities		Dancing, trance performances and ritual curing (Year-round)

Abundance and variety of resources

It is impossible to define 'abundance' of resources absolutely. However, one index of *relative* abundance is whether or not a population exhausts all the food available from a given area. By this criterion, the habitat of the Dobe-area Bushmen is abundant in naturally occurring foods. By far the most important food is the Mongongo (mangetti) nut (*Ricinodendron rautanenii* Schinz). Although tens of thousands of pounds of these nuts are harvested and eaten each year, thousands more rot on the ground each year for want of picking.

The mongongo nut, because of its abundance and reliability, alone accounts for 50 per cent of the vegetable diet by weight. In this respect it resembles a cultivated staple crop such as maize or rice. Nutritionally it is even more remarkable, for it contains five times the calories and ten times the proteins per cooked unit of the cereal crops. The average daily per-capita consumption of 300 nuts yields about 1260 calories and 56 grammes (g) of protein. This modest portion, weighing only about 7.5 ounces, contains the caloric equivalent of 2.5 pounds of cooked rice and the protein equivalent of 14 ounces of lean beef (Watt and Merrill, 1963).

Furthermore the mongongo nut is drought resistant and it will still be abundant in the dry years when cultivated crops may fail. The extremely hard outer shell protects the inner kernel from rot and allows the nuts to be harvested for up to 12 months after they have fallen to the ground. A diet based on mongongo nuts is in fact more reliable than one based on cultivated foods, and it is not surprising, therefore, that when a Bushman was asked why he hadn't taken to agriculture he replied: 'Why should we plant, when there are so many mongongo nuts in the world?'

Apart from the mongongo, the Bushmen have available 84 other species of edible food plants, including 29 species of fruits, berries and melons and 30 species of roots and bulbs. The existence of this variety allows for a wide range of alternatives in subsistence strategy. During the summer months the Bushmen have no problem other than to choose among the tastiest and most easily collected foods. Many species, which are quite edible but less attractive, are bypassed, so that gathering never exhausts *all* the available plant foods of an area. During the dry season the diet becomes much more eclectic and the many species of roots, bulbs and edible resins make an important contribution. It is this broad base that provides an essential margin of safety during the end of the dry season when the mongongo nut forests are difficult to reach. In addition, it is likely that these rarely utilized species provide important nutritional and mineral trace elements that may be lacking in the more popular foods.

Diet selectivity

If the Bushmen were living close to the 'starvation' level, then one would expect them to exploit every available source of nutrition. That their life is well above this level is indicated by the data in Table 1.3. Here all the edible plant species are

[b] 23 species constitutes 90 per cent of the vegetable diet by weight.
[c] 62 species constitutes the remaining 10 per cent of the diet.

arranged in classes according to the frequency with which they were observed to be eaten. It should be noted, that although there are some 85 species available, about 90 per cent of the vegetable diet by weight is drawn from only 23 species. In other words, 75 per cent of the listed species provide only 10 per cent of the food value.

In their meat-eating habits, the Bushmen show a similar selectivity. Of the 223 local species of animals known and named by the Bushmen, 54 species are classified as edible, and of these only 17 species were hunted on a regular basis.[4] Only a handful of the dozens of edible species of small mammals, birds, reptiles and insects that occur locally are regarded as food. Such animals as rodents, snakes, lizards, termites and grasshoppers, which in the literature are included in the Bushman dietary (Schapera, 1930), are despised by the Bushmen of the Dobe area.

Range size and population density

The necessity to travel long distances, the high frequency of moves, and the maintenance of populations at low densities are also features commonly associated with the hunting and gathering way of life. Density estimates for hunters in western North America and Australia have ranged from 3 persons/square mile to as low as 1 person/100 square miles (Kroeber, 1939; Radcliffe-Brown, 1930). In 1963–1965, the resident and visiting Bushmen were observed to utilize an area of about 1000 square miles during the course of the annual round for an effective population density of 41 persons/100 square miles. Within this area, however, the amount of ground covered by members of an individual camp was surprisingly small. A day's round-trip of 12 miles serves to define a 'core' area 6 miles in radius surrounding each water point. By fanning out in all directions from their well, the members of a camp can gain access to the food resources of well over 100 square miles of territory within a two-hour hike. Except for a few weeks each year, areas lying beyond this 6-mile radius are rarely utilized, even though they are no less rich in plants and game than are the core areas.

Although the Bushmen move their camps frequently (five or six times a year) they do not move them very far. A rainy season camp in the nut forests is rarely more than 10 or 12 miles from the home waterhole, and often new campsites are occupied only a few hundred yards away from the previous one. By these criteria, the Bushmen do not lead a free-ranging nomadic way of life. For example, they do not undertake long marches of 30 to 100 miles to get food, since this task can be readily fulfilled within a day's walk of home base. When such long marches do occur they are invariably for visiting, trading and marriage arrangements, and should not be confused with the normal routine of subsistence.

Demographic factors

Another indicator of the harshness of a way of life is the age at which people die. Ever since Hobbes characterized life in the state of nature as 'nasty, brutish and short', the assumption has been that hunting and gathering is so rigorous that members of such societies are rapidly worn out and meet an early death. Silberbauer, for example, says of the Gwi Bushmen of the central Kalahari that 'life expectancy … is difficult to calculate, but I do not believe that many live beyond 45' (1965, p17). And Coon has said of the hunters in general:

> The practice of abandoning the hopelessly ill and aged has been observed in many parts of the world. It is always done by people living in poor environments where it is necessary to move about frequently to obtain food, where food is scarce, and transportation difficult … Among peoples who are forced to live in this way the oldest generation, the generation of individuals who have passed their physical peak is reduced in numbers and influence. There is no body of elders to hand on tradition and control the affairs of younger men and women, and no formal system of age grading (1948, p55).

The !Kung Bushmen of the Dobe area flatly contradict this view. In a total population of 466, no fewer than 46 individuals (17 men and 29 women) were determined to be over 60 years of age, a proportion that compares favourably to the percentage of elderly in industrialized populations.

The aged hold a respected position in Bushman society and are the effective leaders of the camps. Senilicide is extremely rare. Long after their productive years have passed, the old people are fed and cared for by their children and grandchildren. The blind, the senile and the crippled are respected for the special ritual and technical skills they possess. For instance, the four elders at !gose waterhole were totally or partially blind, but this handicap did not prevent their active participation in decision making and ritual curing.

Another significant feature of the composition of the work force is the late assumption of adult responsibility by the adolescents. Young people are not expected to provide food regularly until they are married. Girls typically marry between the ages of 15 and 20, and boys about five years later, so that it is not unusual to find healthy, active teenagers visiting from camp to camp while their older relatives provide food for them.

As a result, the people in the age group 20–60 support a surprisingly large percentage of non-productive young and old people. About 40 per cent of the population in camps contribute little to the food supplies. This allocation of work to young and middle-aged adults allows for a relatively carefree childhood and adolescence and a relatively unstrenuous old age.

Leisure and work

Another important index of ease or difficulty of subsistence is the amount of time devoted to the food quest.[5] Hunting has usually been regarded by social scientists as a way of life in which merely keeping alive is so formidable a task that members of such societies lack the leisure time necessary to 'build culture'.[6] The !Kung Bushmen would appear to conform to the rule, for as Lorna Marshall says:

> It is vividly apparent that among the !Kung Bushmen, ethos, or 'the spirit which actuates manners and customs,' is survival. Their time and energies are almost wholly given to this task, for life in their environment requires that they spend their days mainly in procuring food (1965, p247).

It is certainly true that getting food is the most important single activity in Bushman life. However this statement would apply equally well to small-scale agricultural and pastoral societies too. How much time is *actually* devoted to the food quest is fortunately an empirical question. And an analysis of the work effort of the Dobe Bushmen shows some unexpected results. From 6 July to 2 August 1964, I recorded all the daily activities of the Bushmen living at the Dobe waterhole. Because of the coming and going of visitors, the camp population fluctuated in size day by day, from a low of 23 to a high of 40, with a mean of 31.8 persons. Each day some of the adult members of the camp went out to hunt and/or gather while others stayed home or went visiting. The daily recording of all personnel on hand made it possible to calculate the number of man-days of work as a percentage of total number of man-days of consumption.

Although the Bushmen do not organize their activities on the basis of a seven-day week, I have divided the data this way to make them more intelligible. The work-week was calculated to show how many days out of seven each adult spent in subsistence activities (Table 1.4, Column 7). Week II has been eliminated from the totals since the investigator contributed food. In week I, the people spent an average of 2.3 days in subsistence activities, in week III, 1.9 days, and in week IV, 3.2 days. In all, the adults of the Dobe camp worked about two and a half days a week. Since the average working day was about six hours long, the fact emerges that !Kung Bushmen of Dobe, despite their harsh environment, devote from 12 to 19 hours a week to getting food. Even the hardest working individual in the camp, a man named ≠oma who went out hunting on 16 of the 28 days, spent a maximum of 32 hours a week in the food quest.

Because the Bushmen do not amass a surplus of foods, there are no seasons of exceptionally intensive activities such as planting and harvesting, and no seasons of unemployment. The level of work observed is an accurate reflection of the effort required to meet the immediate caloric needs of the group. This work diary covers the mid-winter dry season, a period when food is neither at its most plentiful nor at its scarcest levels, and the diary documents the transition from better to worse conditions (see Table 1.2). During the fourth week the gatherers were making overnight trips to camps in the mongongo nut forests seven to ten miles distant from the waterhole. These longer trips account for the rise in the level of work, from 12 or 13 to 19 hours per week.

If food getting occupies such a small proportion of a Bushman's waking hours, then how *do* people allocate their time? A woman gathers on one day enough food to feed her family for three days, and spends the rest of her time resting in camp, doing embroidery, visiting other camps or entertaining visitors from other camps. For each day at home, kitchen routines, such as cooking, nut cracking, collecting

Table 1.4 *Summery of Dobe work diary*

[a] See text

Key: Column 1: Mean group size $= \dfrac{\text{total man-days of consumption}}{7}$.

Column 7: Work week = the number of work days per adult per week.

Column 8: Index of subsistence effort $= \dfrac{\text{man-days of work}}{\text{man-days of consumption}}$ (e.g., in Week I, the value of 'S' = .21, i.e., 21 days of work/100 days of consumption or 1 work day produces food for 5 consumption days).

firewood and fetching water, occupy one to three hours of her time. This rhythm of steady work and steady leisure is maintained throughout the year.

The hunters tend to work more frequently than the women, but their schedule is uneven. It is not unusual for a man to hunt avidly for a week and then do no hunting at all for two or three weeks. Since hunting is an unpredictable business and subject to magical control, hunters sometimes experience a run of bad luck and stop hunting for a month or longer. During these periods, visiting, entertaining and especially dancing are the primary activities of men. (Unlike the Hadza, gambling is only a minor leisure activity.)

The trance-dance is the focus of Bushman ritual life; over 50 per cent of the men have trained as trance-performers and regularly enter trance during the course of the all-night dances. At some camps, trance-dances occur as frequently as two or three times a week and those who have entered trances the night before rarely go out hunting the following day. Accounts of Bushman trance performances have been published in Lorna Marshall (1962) and Lee (1967). In a camp with five or more hunters, there are usually two or three who are actively hunting and several others who are inactive. The net effect is to phase the hunting and non-hunting so that a fairly steady supply of meat is brought into a camp.

Caloric returns

Is the modest work effort of the Bushmen sufficient to provide the calories necessary to maintain the health of the population? Or have the !Kung, in common with some agricultural peoples (see Richards, 1939), adjusted to a permanently substandard nutritional level?

During my fieldwork I did not encounter any cases of kwashiorkor, the most common nutritional disease in the children of African agricultural societies. However, without medical examinations, it is impossible to exclude the possibility that subclinical signs of malnutrition existed.[7]

Another measure of nutritional adequacy is the average consumption of calories and proteins per person per day. The estimate for the Bushmen is based on observations of the weights of foods of known composition that were brought into Dobe camp on each day of the study period. The per-capita figure is obtained by dividing the total weight of foodstuffs by the total number of persons in the camp. These results are set out in detail elsewhere (Lee, in press) and can only be summarized here. During the study period 410 pounds of meat were brought in by the hunters of the Dobe camp, for a daily share of nine ounces of meat per person. About 700 pounds of vegetable foods were gathered and consumed during the same period. Table 1.5 sets out the calories and proteins available per capita in the !Kung Bushman dietary from meat, mongongo nuts and other vegetable sources.

This output of 2140 calories and 93.1 grams of protein per person per day may be compared with the Recommended Daily Allowances (RDA) for persons of the small size and stature but vigorous activity regime of the !Kung Bushmen. The RDA for Bushmen can be estimated at 1975 calories and 60 grams of protein per

Table 1.5 *Caloric and protein levels in the !Kung Bushman dietary, July–August 1964*

Class of food	Percentage contribution to diet by weight	Per capita consumption			Percentage caloric contribution of meat and vegetables
		Weight in grams	Protein in grams	Calories per person per day	
Meat	37	230	34.5	690	33
Mongongo nuts	33	210	56.7	1260	67
Other vegetable foods	30	190	1.9	190	
Total All sources	100	630	93.1	2140	100

person per day. (Taylor and Pye, 1966, pp45–48, 463). Thus it is apparent that food output exceeds energy requirements by 165 calories and 33 grams of protein. One can tentatively conclude that even a modest subsistence effort of two or three days work per week is enough to provide an adequate diet for the !Kung Bushmen.

The Security of Bushman Life

I have attempted to evaluate the subsistence base of one contemporary hunter-gatherer society living in a marginal environment. The !Kung Bushmen have available to them some relatively abundant high-quality foods, and they do not have to walk very far or work very hard to get them. Furthermore this modest work effort provides sufficient calories to support not only the active adults, but also a large number of middle-aged and elderly people. The Bushmen do not have to press their youngsters into the service of the food quest, nor do they have to dispose of the oldsters after they have ceased to be productive.

The evidence presented assumes an added significance because this security of life was observed during the third year of one of the most severe droughts in South Africa's history. Most of the 576,000 people of Botswana are pastoralists and agriculturalists. After the crops had failed three years in succession and over 100,000 head of cattle had died on the range for lack of water, the World Food Program of the United Nations instituted a famine relief programme which has grown to include 180,000 people, over 30 per cent of the population (Government of Botswana, 1966). This programme did not touch the Dobe area in the isolated northwest corner of the country and the Herero and Tswana women there were able to feed their families only by joining the Bushman women to forage for wild foods. Thus the natural plant resources of the Dobe area were carrying a higher proportion of population than would be the case in years when the Bantu harvested crops. Yet this added pressure on the land did not seem to adversely affect the Bushmen.

In one sense it was unfortunate that the period of my fieldwork happened to coincide with the drought, since I was unable to witness a 'typical' annual subsistence cycle. However, in another sense, the coincidence was a lucky one, for the drought put the Bushmen and their subsistence system to the acid test and, in terms of adaptation to scarce resources, they passed with flying colours. One can postulate that their subsistence base would be even more substantial during years of higher rainfall.

What are the crucial factors that make this way of life possible? I suggest that the primary factor is the Bushmen's strong emphasis on vegetable food sources. Although hunting involves a great deal of effort and prestige, plant foods provide from 60–80 per cent of the annual diet by weight. Meat has come to be regarded as a special treat; when available, it is welcomed as a break from the routine of vegetable foods, but it is never depended upon as a staple. No one ever goes hungry when hunting fails.

The reason for this emphasis is not hard to find. Vegetable foods are abundant, sedentary and predictable. They grow in the same place year after year, and the gatherer is guaranteed a day's return of food for a day's expenditure of energy. Game animals, by contrast, are scarce, mobile, unpredictable and difficult to catch. A hunter has no guarantee of success and may in fact go for days or weeks without killing a large mammal. During the study period, there were 11 men in the Dobe camp, of whom four did no hunting at all. The seven active men spent a total of 78 man-days hunting, and this work input yielded 18 animals killed, or one kill for every four man-days of hunting. The probability of any one hunter making a kill on a given day was 0.23. By contrast, the probability of a woman finding plant food on a given day was 1.00. In other words, hunting and gathering are not equally felicitous subsistence alternatives.

Consider the productivity per man-hour of the two kinds of subsistence activities. One man-hour of hunting produces about 100 edible calories, and of gathering, 240 calories. Gathering is thus seen to be 2.4 times more productive than hunting. In short, hunting is a *high-risk*, *low-return* subsistence activity, while gathering is a *low-risk*, *high-return* subsistence activity.

It is not at all contradictory that the hunting complex holds a central place in the Bushman ethos and that meat is valued more highly than vegetable foods (Marshall, 1960). Analogously, steak is valued more highly than potatoes in the food preferences of our own society. In both situations the meat is more 'costly' than the vegetable food. In the Bushman case, the cost of food can be measured in terms of time and energy expended. By this standard, 1000 calories of meat 'costs' 10 man-hours, while the 'cost' of 1000 calories of vegetable foods is only four man-hours. Further, it is to be expected that the less predictable, more expensive food source would have a greater accretion of myth and ritual built up around it than would the routine staples of life, which rarely if ever fail.

Eskimo–Bushman comparisons

Were the Bushmen to be deprived of their vegetable food sources, their life would become much more arduous and precarious. This lack of plant foods, in fact, is precisely the situation among the Netsilik Eskimo, reported by Balikci (1968). The Netsilik and other Central Arctic peoples are perhaps unique in the almost total absence of vegetable foods in their diet. This factor, in combination with the great cyclical variation in the numbers and distribution of Arctic fauna, makes Eskimo life the most precarious human adaptation on earth. In effect, *the kinds of animals that are 'luxury goods' to many hunters and gatherers, are to the Eskimos, the absolute necessities of life*. However, even this view should not be exaggerated, since most of the Eskimos in historic times have lived south of the Arctic Circle (Laughlin, 1968) and many of the Eskimos at all latitudes have depended primarily on fishing, which is a much more reliable source of food than is the hunting of land and sea mammals.

What Hunters Do for a Living: A Comparative Study

I have discussed how the !Kung Bushmen are able to manage on the scarce resources of their inhospitable environment. The essence of their successful strategy seems to be that while they depend primarily on the more stable and abundant food sources (vegetables in their case), they are nevertheless willing to devote considerable energy to the less reliable and more highly valued food sources such as medium and large mammals. The steady but modest input of work by the women provides the former, and the more intensive labours of the men provide the latter. It would be theoretically possible for the Bushmen to survive entirely on vegetable foods, but life would be boring indeed without the excitement of meat feasts. The totality of their subsistence activities thus represents an outcome of two individual goals; the first is the desire to live well with adequate leisure time, and the second is the desire to enjoy the rewards, both social and nutritional, afforded by the killing of game. In short, *the Bushmen of the Dobe area eat as much vegetable food as they need, and as much meat as they can.*

It seems reasonable that a similar kind of subsistence strategy would be characteristic of hunters and gatherers in general. Wherever two or more kinds of natural foods are available, one would predict that the population exploiting them would emphasize the more reliable source. We would also expect, however, that the people would not neglect the alternative means of subsistence. The general view offered here is that gathering activities, for plants and shellfish, should be the most productive of food for hunting and gathering man, followed by fishing, where this source is available. The hunting of mammals is the least reliable source of food and should be generally less important than either gathering or fishing.

In order to test this hypothesis, a sample of 58 societies was drawn from the *Ethnographic Atlas* (Murdock, 1967). The basis for inclusion in the sample was a

100 per cent dependence on hunting, gathering and fishing for subsistence as rated in Columns 7–11 of the Atlas (Murdock, 1967, pp154–155). These 58 societies are plotted in Figures 1.1 and 1.2 and are listed in Tables 1.7 and 1.8 of the Appendix to this chapter.[8, 9]

The *Ethnographic Atlas* coding discusses 'Subsistence Economy' as follows:

> A set of five digits indicates the estimated relative dependence of the society on each of the five major types of subsistence activity. The first digit refers to the gathering of wild plants and small land fauna; the second, to hunting, including trapping and fowling; the third, to fishing, including shell fishing and the pursuit of large aquatic animals; the fourth, to animal husbandry; the fifth, to agriculture (Murdock, 1967, pp154–55).

Two changes have been made in the definitions of subsistence. First, the participants at the symposium on Man the Hunter agreed that the 'pursuit of large aquatic animals' is more properly classified under hunting than under fishing. Similarly, it was recommended that shellfishing should be classified under gathering, not fishing. These suggestions have been followed and the definitions now read: *Gathering* – collecting of wild plant, small land fauna and shellfish; *Hunting* – pursuit of land and sea mammals; *Fishing* – obtaining of fish by any technique. In 25 cases, the subsistence scores have been changed in light of these definitions and after consulting ethnographic sources.[10]

In Tables 1.9 and 1.10 of the Appendix to this article, the percentage dependence on gathering, hunting and fishing, and the most important single source of food for each society are presented. Such scores can be at best only rough approximations; however, the results are so striking that the use of these scores seems justified. In the Old World and South American sample of 24 societies, 16 depend on gathering, five on fishing, while only three depend primarily on mammal hunting: the Yukaghir of northeast Asia, and the Ona and Shiriana of South America. In the North American sample, 13 societies have primary dependence on gathering, 13 on fishing, and eight on hunting. Thus for the world as a whole, half of the societies (29 cases) emphasize gathering, one-third (18 cases) fishing, and the remaining one-sixth (11 cases) hunting.

On this evidence, the 'hunting' way of life appears to be in the minority. The result serves to underline the point made earlier that mammal hunting is the least reliable of the subsistence sources, and one would expect few societies to place primary dependence on it. As will be shown, most of the societies that rely primarily on mammals do so because their particular habitats offer no viable alternative subsistence strategy.

The relation of latitude to subsistence

The peoples we have classified as 'hunters' apparently depend for most of their subsistence on sources *other* than meat, namely, wild plants, shellfish and fish. In fact the present sample over-emphasizes the incidence of hunting and fishing since

Table 1.6 *Primary subsistence source by latitude*

Degrees from the equator	*Primary subsistence source*			
	Gathering	*Hunting*	*Fishing*	*Total*
More than 60°	—	6	2	8
50°–59°	—	1	9	10
40°–49°	4	3	5	12
30°–39°	9	—	—	9
20°–29°	7	—	1	8
10°–19°	5	—	1	6
0°–9°	4	1	—	5
World	29	11	18	58

some three-fifths of the cases (34/58) are drawn from North America (north of the Rio Grande) a region which lies entirely within the temperate and arctic zones. Since the abundance and species variety of edible plants decreases as one moves out of the tropical and temperate zones, and approaches zero in the arctic, it is essential that the incidence of hunting, gathering and fishing be related to latitude.

Table 1.6 shows the relative importance of gathering, hunting and fishing within each of seven latitude divisions. Hunting appears as the dominant mode of subsistence *only* in the highest latitudes (60 or more degrees from the equator). In the arctic, hunting is primary in six of the eight societies. In the cool to cold temperate latitudes, 40 to 59 degrees from the equator, fishing is the dominant mode, appearing as primary in 14 out of 22 cases. In the warm-temperate, subtropical and tropical latitudes, zero to 39 degrees from the equator, gathering is by far the dominant mode of subsistence, appearing as primary in 25 of the 28 cases.

For modern hunters, at any rate, it seems legitimate to predict a hunting emphasis only in the arctic, a fishing emphasis in the mid–high latitudes, and a gathering emphasis in the rest of the world.[11]

The importance of hunting

Although hunting is rarely the primary source of food, it does make a remarkably stable contribution to the diet. Fishing appears to be dispensable in the tropics, and a number of northern peoples manage to do without gathered foods, but, with a single exception, *all* societies at all latitudes derive at least 20 per cent of their diet from the hunting of mammals. Latitude appears to make little difference in the amount of hunting that people do. Except for the highest latitudes, where hunting contributes over half of the diet in many cases, hunted foods almost everywhere else constitute 20 to 45 per cent of the diet. In fact, the mean, the median and the mode for hunting all converge on a figure of 35 per cent for hunter-gatherers at all latitudes. This percentage of meat corresponds closely to the 37 per cent noted in the diet of the !Kung Bushmen of the Dobe area. It is evident that the !Kung, far from being an aberrant case, are entirely typical of the hunters in general in the amount of meat they consume.

Conclusions

Three points ought to be stressed. First, life in the state of nature is not necessarily nasty, brutish and short. The Dobe-area Bushmen live well today on wild plants and meat, in spite of the fact that they are confined to the least productive portion of the range in which Bushman peoples were formerly found. It is likely that an even more substantial subsistence base would have been characteristic of these hunters and gatherers in the past, when they had the pick of African habitats to choose from.

Second, the basis of Bushman diet is derived from sources other than meat. This emphasis makes good ecological sense to the !Kung Bushmen and appears to be a common feature among hunters and gatherers in general. Since a 30 to 40 per cent input of meat is such a consistent target for modern hunters in a variety of habitats, is it not reasonable to postulate a similar percentage for prehistoric hunters? Certainly the absence of plant remains on archaeological sites is by itself not sufficient evidence for the absence of gathering. Recently abandoned Bushman campsites show a similar absence of vegetable remains, although this paper has clearly shown that plant foods comprise over 60 per cent of the actual diet.

Finally, one gets the impression that hunting societies have been chosen by ethnologists to illustrate a dominant theme, such as the extreme importance of environment in the moulding of certain cultures. Such a theme can be best exemplified by cases in which the technology is simple and/or the environment is harsh. This emphasis on the dramatic may have been pedagogically useful, but unfortunately it has led to the assumption that a precarious hunting subsistence base was characteristic of all cultures in the Pleistocene. This view of both modern and ancient hunters ought to be reconsidered. Specifically I am suggesting a shift in focus away from the dramatic and unusual cases, and towards a consideration of hunting and gathering as a persistent and well-adapted way of life.

Notes

1 These data are based on 15 months of field research from October 1963, to January 1965. I would like to thank the National Science Foundation (US) for its generous financial support. This paper has been substantially revised since being presented at the symposium on Man the Hunter.

2 The Nyae Nyae !Kung Bushmen studied by Lorna Marshall (1957, 1960, 1965) have been involved in a settlement scheme instituted by the South African government. Although closely related to the Nyae Nyae !Kung, the Dobe !Kung across the border in Botswana have not participated in the scheme.

3 Bushman group structure is discussed in more detail in Lee (1965, pp38–53; and Chapter 17c, this volume).

4 Listed in order of their importance, the principal species in the diet are: wart hog, kudu, duiker, steenbok, gemsbok, wildebeeste, springhare, porcupine, ant bear, hare, guinea fowl, francolin (two species), korhaan, tortoise and python.

5 This and the following topic are discussed in greater detail in Lee, '!Kung Bushman Subsistence: An Input-Output Analysis' (in press).

6 Lenski, for example, in a recent review of the subject, states: 'Unlike the members of hunting and gathering societies [the horticulturalists] are not compelled to spend most of their working hours in the search for food and other necessities of life, but are able to use more of their time in other ways' (1966, p121).

7 During future fieldwork with the !Kung Bushmen, a professional paediatrician and nutritionist are planning to examine children and adults as part of a general study of hunter-gatherer health and nutrition sponsored by the US National Institutes of Health and the Wenner-Gren Foundation for Anthropological Research.

8 Two societies, the Gwi Bushmen and the Walbiri of Australia, were not coded by the *Ethnographic Atlas*. Their subsistence base was scored after consulting the original ethnographies (for the Gwi, Silberbauer, 1965; for the Walbiri, Meggitt, 1962, 1964).

9 In order to make more valid comparisons, I have excluded from the sample mounted hunters with guns such as the Plains Indians, and casual agriculturalists such as the Gê and Siriono. Twenty-four societies are drawn from Africa, Asia, Australia and South America. This number includes practically all of the cases that fit the definition. North America alone, with 137 hunting societies, contains over 80 per cent of the 165 hunting societies listed in the *Ethnographic Atlas*. The sampling procedure used here was to choose randomly one case from each of the 34 'clusters' of North American hunter-gatherers.

10 For their useful suggestions, my thanks go to Donald Lathrap, Robin Ridington, George Silberbauer, Hitoshi Watanabe and James Woodburn. Special thanks are due to Wayne Suttles for his advice on Pacific coast subsistence.

11 When severity of winter is plotted against subsistence choices, a similar picture emerges. Hunting is primary in three of the five societies in very cold climates (annual temperature less than 32° F); fishing is primary in 10 of the 17 societies in cold climates (32°–50° F); and gathering is primary in 27 of the 36 societies in mild to hot climates (over 50° F).

Foragers and Others

Richard B. Lee and Richard Daly

Recently an aboriginal guide was showing a group of tourists around Alberta's renowned Head-Smashed-In Buffalo-Jump, a UNESCO World Heritage Site staffed by First Nations personnel. The guide graphically described how in ancient times the buffalo would be driven over the edge of a 15-metre precipice, to land in a gory heap at the base of the cliff. A diorama showed men and women clambering over the bodies to club and spear those still living. When one tourist expressed shock at the bloody nature of the enterprise, the guide responded simply but with conviction, 'We were hunters!' connecting her own generation with those of the past. She then amended her statement with equal conviction, adding, 'Humans were hunters!' thus expanding complicity in the act of carnage to the whole of humanity, not excluding her interlocutor.

This incident summarizes neatly the historical conjuncture that brings *The Cambridge Encyclopedia of Hunters and Gatherers* to fruition. The world's hunting and gathering peoples – the Arctic Inuit, Aboriginal Australians, Kalahari San and similar groups – represent the oldest and perhaps most successful human adaptation. Until 12,000 years ago virtually all humanity lived as hunters and gatherers. In recent centuries hunters have retreated precipitously in the face of the steamroller of modernity. However, fascination with hunting peoples and their ways of life remains strong, a fascination tinged with ambivalence. The reason for public and academic interest is not hard to find. Hunters and gatherers stand at the opposite pole from the dense urban life experienced by most of humanity. Yet these same hunters may hold the key to some of the central questions about the human condition – about social life, politics and gender, about diet and nutrition and living in nature: how people can live and have lived without the state; how to live without accumulated technology; the possibility of living in Nature without destroying it. This book offers no simple answers to these questions. Hunter-gatherers are a diverse group of peoples living in a wide range of conditions. One of the themes of the book is the exploration of that diversity. Yet within the range

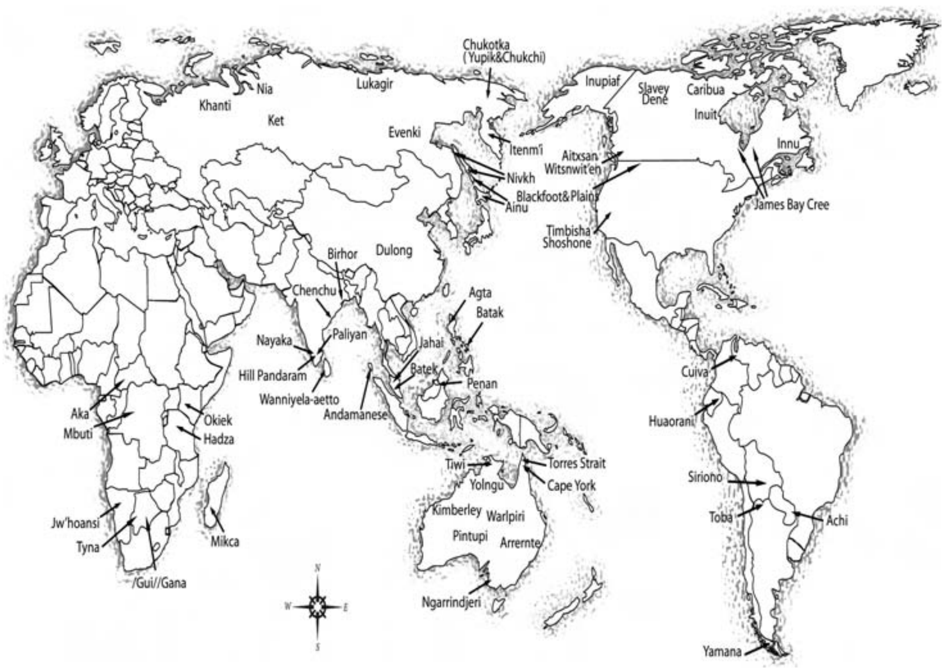
Lee R B and Daly R. Foragers and others. In Lee R B and Daly R (eds). *Cambridge Encyclopedia of Hunters and Gatherers*, 1999, Cambridge University Press, Cambridge.

of variation, certain common motifs can be identified. Hunter-gatherers are generally peoples who have lived until recently without the overarching discipline imposed by the state. They have lived in relatively small groups, without centralized authority, standing armies or bureaucratic systems. Yet the evidence indicates that they have lived together surprisingly well, solving their problems among themselves largely without recourse to authority figures and without a particular propensity for violence. It was not the situation that Thomas Hobbes, the great 17th-century philosopher, described in a famous phrase as 'the war of all against all'. By all accounts life was not 'nasty, brutish and short'. With relatively simple technology – wood, bone, stone, fibres – they were able to meet their material needs without a great expenditure of energy, leading the American anthropologist and social critic Marshall Sahlins to call them, in another famous phrase, 'the original affluent society'. Most striking, the hunter-gatherers have demonstrated the remarkable ability to survive and thrive for long periods – in some cases thousands of years – without destroying their environment.

The contemporary industrial world lives in highly structured societies at immensely higher densities and enjoys luxuries of technology that foragers could hardly imagine. Yet all these same societies are sharply divided into haves and have-nots, and after only a few millennia of stewardship by agricultural and industrial civilizations, the environments of large parts of the planet lie in ruins. Therefore the hunter-gatherers may well be able to teach us something, not only about past ways of life but also about long-term human futures. If technological humanity is to survive it may have to learn the keys to longevity from fellow humans whose way of life has been around a lot longer than industrial commercial 'civilization'. As Burnum Burnum, the late Australian Aboriginal writer and lecturer, put it, 'Modern ecology can learn a great deal from a people who managed and maintained their world so well for 50,000 years.'

Hunter-gatherers in recent history have been surprisingly persistent. As recently as AD 1500 hunters occupied fully one-third of the globe, including all of Australia and most of North America, as well as large tracts of South America, Africa and North-east Asia. The 20th century has seen particularly dramatic changes in their life circumstances. The century began with dozens of hunting and gathering peoples still pursuing ancient (though not isolated) lifeways in small communities, as foragers with systems of local meaning centred on kin, plants, animals and the spirit world. As the century proceeded, a wave of self-appointed civilizers washed over the world's foragers, bringing schools, clinics and administrative structures, and, not incidentally, taking their land and resources.

The year 2000 will have seen the vast majority of former foragers settled and encapsulated in the administrative structures of one state or another. And given their tragic history of forced acculturation one would imagine that the millennium will bring to a close a long chapter in human history. But will it? We believe not. Hunter-gatherers live on, not only in the pages of anthropological and historical texts, but also, in 40 countries, in the presence of hundreds of thousands of descendants a generation or two removed from a foraging way of life, and these



Map 2.1 *Case studies in the* Cambridge Encyclopedia of Hunters and Gatherers

peoples and their supporters are creating a strong international voice for indigenous peoples and their human rights.

Among the public-at-large, images of hunters and gatherers have swung between two poles. For centuries they were regarded as 'savages', variously ignorant or cunning, beyond the pale of 'civilization'. This distorted image was usually associated with settler societies who coveted the foragers' land; the negative stereotypes justified dispossession.

In recent years a different view has dominated, with hunter-less gatherers as the repository of virtues seemingly lacking in the materialism and marked inequalities of contemporary urban life. How to balance these two views? For many current observers the contrast between savage inequities of modernity and the relative egalitarianism of the so-called 'primitives' gives the latter more weight on the scales of natural justice. Jack Weatherford's eloquently argued book, *Savages and Civilization: Who Will Survive?* (1994), draws on a long intellectual tradition dating from Rousseau which, contemplating the horrors of the modern world, raises the question of who are the truly civilized: the 'savage' with his occasional blood-feud, or the 'civilized' who gave the world the Inquisition, the Atlantic slave trade, the Catling gun, napalm, Hiroshima and the Holocaust? (For an opposing view see Robert Edgerton's *Sick Societies* [1992].)

The present work thus grows out of the intersection between three discourses: anthropological knowledge, public fascination and indigenous peoples' own worldviews. The *Encyclopedia* speaks to scholars, to general readers, and particularly to the members of the cultures themselves. The book offers an up-to-date and encyclopedic inventory of hunters and gatherers, written in accessible language by recognized authorities, some of whom are representatives of the cultures they write about.

Foraging Defined

Foraging refers to subsistence based on hunting of wild animals, gathering of wild plant foods, and fishing, with no domestication of plants, and no domesticated animals except the dog. In contemporary theory this minimal definition is only the starting point in defining hunter-gatherers. Recent research has brought a more nuanced understanding of the issue of who the hunters are and why they have persisted. While it is true that hunting and gathering represent the original condition of humankind and 90 per cent of human history, the contemporary people called hunter-gatherers arrived at their present condition by a variety of pathways.

At one end of a continuum are the areas of the world where modern hunter-gatherers have persisted in a more or less direct tradition of descent from ancient hunter-gatherer populations. This would characterize the aboriginal peoples of Australia, north-western North America, the southern cone of South America and pockets in other world areas. The Australian Pintupi, Arrernte and Warlpiri, the North American Eskimo, Shoshone and Cree, the South American Yamana, and the African Ju/'hoansi are examples of this first grouping, represented in case studies in this volume. In pre-colonial Australia and parts of North America we come closest to Marshall Sahlins' rubric of 'hunters in a world of hunters' (Lee and DeVore 1968). But even here the histories offer examples of complex interrelations between foragers and others.

Along the middle of the continuum are hunting and gathering peoples who have lived in degrees of contact and integration with non-hunting societies, and these include a number whose own histories include life as farmers and/or herders in the past. South and South-east Asian hunter-gatherers are linked to settled villagers and their markets, trading forest products: furs, honey, medicinal plants and rattan, for rice, metals and consumer goods. Some of these arrangements have persisted for millennia. Similar arrangements are seen in central Africa where Pygmies have lived for centuries in patron–client relations with settled villagers while still maintaining a period of the year when they lived more autonomously in the forest. And in East Africa the foraging Okiek traditionally supplied honey and other forest products to neighbouring Maasai and Kipsigis.

South American hunter-gatherers present an even more interesting case, since archaeological evidence indicates that in Amazonia farming replaced foraging several millennia ago. In the view of Anna Roosevelt, much of the foraging observed in *tropical* South America represents a secondary readaptation. After the European conquests of the 16th–18th centuries many groups found that mobile hunting and gathering made them less vulnerable to colonial exploitation. Other groups had been operating this way far longer, back into the pre-colonial period. And almost all *tropical* South American foragers today plant gardens as one part of their annual trek. There are parallels here with Siberia, where most of the 'small peoples' classified as hunter-gatherers also herded reindeer, a practice which greatly expanded during the Soviet period.

Finally, at the other end of the continuum are peoples who once were hunters but who changed their subsistence in the more distant past. And that includes the rest of us: the 5-billion-strong remainder of humanity.

Social Life

In defining foragers we must recognize that contemporary foragers practise a mixed subsistence: gardening in tropical South America, reindeer herding in northern Asia, trading in South/South-east Asia and parts of Africa. Given this diversity, what constitutes the category 'hunter-gatherer'? The answer is that subsistence is one part of a multifaceted definition of hunter-gatherers: social organization forms a second major area of convergence, and cosmology and worldview a third. All three sets of criteria have to be taken into account in understanding hunting and gathering peoples today.

The basic unit of social organization of most (but not all) hunting and gathering peoples is the *band*, a small-scale nomadic group of 15–50 people related by kinship. Band societies are found throughout the Old and New Worlds and share a number of features in common. Most observers would agree that the social and economic life of *small-scale* hunter-gatherers shares the following features.

First they are relatively *egalitarian*. Leadership is less formal and more subject to constraints of popular opinion than in village societies governed by headmen and chiefs. Leadership in band societies tends to be by example, not by fiat. The leader can persuade but not command. This important aspect of their way of life allowed for a degree of freedom unheard of in more hierarchical societies but it has put them at a distinct disadvantage in their encounters with centrally organized colonial authorities.

Mobility is another characteristic of band societies. People tend to move their settlements frequently, several times a year or more, in search of food, and this mobility is an important element of their politics. People in band societies tend to 'vote with their feet', moving away rather than submitting to the will of an unpopular leader. Mobility is also a means of resolving conflicts that would be more difficult for settled peoples.

A third characteristic is the remarkable fact that all band-organized peoples exhibit a pattern of *concentration and dispersion*. Rather than living in uniformly sized groupings throughout the year, band societies tend to spend part of the year dispersed into small foraging units and another part of the year aggregated into much larger units. The Innu (Naskapi) discussed by Mailhot would spend the winter dispersed in small foraging groups of 10–30, while in the summer they would aggregate in groups of up to 200–300 at lake or river fishing sites. It seems clear that the concentration/dispersion patterns of hunter-gatherers represent a dialectical interplay of social *and* ecological factors.

A fourth characteristic common to almost all band societies (and hundreds of village-based societies as well) is a land tenure system based on a *common property regime (CPR)*. These regimes were, until recently, far more common worldwide than regimes based on private property. In traditional CPRs, while movable property is held by individuals, land is held by a kinship-based collective. Rules of reciprocal access make it possible for each individual to draw on the resources of several territories. Rarer is the situation where the whole society has unrestricted access to all the land controlled by the group.

Ethos and Worldview

Another broad area of commonalities lies in the domains of the quality of interpersonal relations and forms of consciousness.

Sharing is the central rule of social interaction among hunters and gatherers. There are strong injunctions on the importance of reciprocity. Generalized reciprocity, the giving of something without an immediate expectation of return, is the dominant form within face-to-face groups. Its presence in hunting and gathering societies is almost universal (Sahlins 1965). This, combined with an absence of private ownership of land, has led many observers from Lewis Henry Morgan forward to attribute to hunter-gatherers a way of life based on 'primitive communism' (Morgan, 1881; Testart, 1985; Lee, 1988).

Found among many but not all hunter-gatherers is the notion of the *giving environment*, the idea that the land around them is their spiritual home and the source of all good things (Turnbull, 1965; Bird-David, 1990). This view is the direct antithesis of the Western Judeo-Christian perspective on the natural environment as a 'wilderness', a hostile space to be subdued and brought to heel by the force of will. This latter view is seen by many ecological humanists as the source of both the environmental crisis and the spiritual malaise afflicting contemporary humanity (Shiva, 1988, 1997; Suzuki, 1989, 1992, 1997).

Hunter-gatherers are peoples who live with nature. When we examine the *cosmology* of hunting and gathering peoples, one striking commonality is the view of nature as animated with moral and mystical force, in Robert Bellah's phrase 'the hovering closeness of the world of myth to the actual world' (1965, p19). As discussed by Mathias Guenther (*Cambridge Encyclopedia of Hunters and Gatherers*), the world of hunter-gatherers is a multilayered world, composed of two or more planes: an above/beyond zone and an underworld in addition to the present world inhabited by humans. There are invariably two temporal orders of existence, with an Early mythical or 'dreamtime' preceding the present. In the former, nature and culture are not yet fully separated. Out of this Ur-existence, a veritable cauldron of cultural possibilities, crystallizes the distinction between humans and animals, the origin of fire, cooking, incest taboos, even mortality itself and virtually everything of cultural significance.

The world of the Past and the above-and-below world of myth are in intimate contact with the normal plane of existence. The Australian Aborigines present the most fully realized instance of this process of world-enchantment. The famous 'songlines' of the Dreamtime criss-cross the landscape and saturate it with significance. Every rock and feature has symbolic meaning and these are bound up in the reproduction of life itself. It is these totemic elements that are the sources of the spirit children that enter women's wombs and trigger conception. Parallels are found in many other hunter-gatherer groups.

The *Trickster* is a central figure in the myth worlds of many hunting and gathering societies. A divine figure, but deeply flawed and very human, the Trickster is found in myth cycles from the Americas, Africa, Australia and Siberia. Similar figures grace the pantheons of most village farming and herding peoples as well. The Trickster symbolizes the frailty and human qualities of the gods and their closeness to humans. These stand in pointed contrast to the omnipotent, all-knowing but distant deities that are central to the pantheons of state religions and their powerful ecclesiastical hierarchies (Radin, 1956; Diamond, 1974; Wallace, 1966).

Shamanism is another major practice common to the great majority of hunting and gathering peoples. The word originates in eastern Siberia, from the Evenki/Tungus word *saman* meaning 'one who is excited or raised'. Throughout the hunter-gatherer world community-based ritual specialists (usually part-time) heal the sick and provide spiritual protection. They mediate between the social/human world and the dangerous and unpredictable world of the supernatural. Shamanism is performative, mixing theatre and instrumental acts in order to approach the plane of the sacred. Performances vary widely. Among the Ju/'hoansi the 'owners of medicine', after a long and difficult training period, enter an altered state of consciousness called *Ikia*, to heal the sick through a laying on of hands (Marshall, 1968; Katz, 1982). The northern Ojibwa practised the famous shaking tent ceremony or *midewiwin*, while other shamans used dreams, psychoactive drugs, or intense mental concentration to reach the sacred plane. The brilliant use of language and metaphor in the form of powerful and moving verbal images is a central part of the shaman's craft (Rothenberg, 1968). So powerful are these techniques that they have been widely and successfully adapted to the *visualization therapies* in the treatment of cancer and other conditions in Western medicine.

Ethos and social organization are both essential components of hunter-gatherer lifeways. Laura Rival (*Cambridge Encyclopedia of Hunters and Gatherers*) makes the point that two South American tropical forest peoples may well have a rather similar subsistence mix, but different orientations: analysing them on the basis of their social organization and mobility patterns, as well as mythology, rituals and inter-personal relations, the researcher finds that one has a clearly agricultural orientation, the other a foraging one.

What is remarkable is that, despite marked differences in historical circumstances, foragers seem to arrive at similar organizational and ideational solutions to the problems of living in groups, a convergence that Tim Ingold, the foremost authority on hunter-gatherer social life, has labelled 'a distinct mode of sociality' (*Cambridge Encyclopedia of Hunters and Gatherers*).

Divergences

Despite these commonalities, there are a number of significant divergences among hunters and gatherers. And consideration of these must temper any attempt to present an idealized picture of foraging peoples. First the foragers as a group are not particularly peaceful. *Interpersonal violence* is documented for most and warfare is recorded for a number of hunting and gathering peoples. Although peaceful peoples such as the Malaysian Semang are celebrated in the literature (Dentan, 1968), for many others (Inupiat, Warlpiri, Blackfoot, Aché, Agta) raids and blood-feuds are common occurrences, particularly before the pacification campaigns of the colonial authorities (see for example Ember, 1992; Moss, 1992; Bamforth, 1994). But mention of the colonial context raises another important issue. Did high levels of 'primitive' warfare represent a primordial condition, or were these exacerbated by the pressure of colonial conquest? The question remains an ongoing subject of debate (Divale and Harris, 1976; Ferguson, 1984).

Gender is another dimension in which hunting and gathering societies show considerable variation. As Karen Endicott argues (*Cambridge Encyclopedia of Hunters and Gatherers*), the women of hunter-gatherer societies *do* have higher status than women in most of the world's societies, including industrial and post-industrial modernity. This status is expressed in greater freedom of movement and involvement in decision making and a lower incidence of domestic violence against them when compared to women in farming, herding, and agrarian societies (Leacock, 1978, 1982; Lee, 1982). Nevertheless variation exists: wife-beating and rape are recorded for societies as disparate as those of Alaska (Eskimo) and northern Australian Aborigines (Friedl, 1975; Abler, 1992) and are not unknown elsewhere; nowhere can it be said that women and men live in a state of perfect equality.

A third area of divergence is found in the important distinction between *simple vs. complex* hunter-gatherers. Price and Brown (1985) argued that not all hunting and gathering peoples – prehistoric and contemporary – lived in small mobile bands. Some, like the Indians of the North-west Coast (Donald, 1984, 1997; Mitchell and Donald, 1985) and the Calusa of Florida (Marquardt, 1988), as well as many prehistoric peoples, lived in large semi-sedentary settlements with chiefs, commoners and slaves, yet were entirely dependent on wild foods. In social organization and ethos these societies showed significant divergence from the patterns outlined above, yet in other ways a basic foraging pattern is discernible. For example the North-west Coast peoples still maintained a concentration–dispersion pattern, breaking down their large permanent plank houses in the summer and incorporating them into temporary structures at seasonal fishing sites (Boas, 1966, Daly, *Cambridge Encyclopedia of Hunters and Gatherers*). A related concept is James Woodburn's notion of *immediate-return vs. delayed-return societies* (1982). Although both were subsumed under the heading of 'band society', in immediate-return societies food was consumed on the spot or soon after, while in delayed-return societies food and other resources might he stored for months or years, with marked effects on social organization and cultural notions of property (Woodburn, 1982).

In a superb synthesis Robert L. Kelly has documented these divergences on many fronts in his book *The Foraging Spectrum: Diversity in Hunter-gatherer Lifeways* (1995). Recently Susan Kent (1996b) has attempted a similar exercise for the diversity and variation in the hunting and gathering societies of a single continent, Africa. The point is that hunter-gatherers encompass a wide range of variability and analysts seeking to make sense of them ignore this diversity at their peril!

The Importance of History

Any adequate representation of hunting and gathering peoples in the 21st century has to address the complex historical circumstances in which they are found. Foragers have persisted to the present for a variety of reasons but all have developed historical links with non-foraging peoples, some extending over centuries or millennia. And all have experienced the transformative effects of colonial conquest and incorporation into states. Situating the foraging peoples in history is thus essential to any deeper understanding of them, a point that was often lost on earlier observers who preferred to treat foragers as unmediated visions of the past.

One recent school of thought has questioned the validity of the very concept 'hunter-gatherer'. Starting from the fact that some hunter-gatherers have been dominated by more powerful outsiders for centuries, proponents of this school see contemporary foraging peoples more as victims of colonialism or subalterns at the bottom of a class structure than as exemplars of the hunting and gathering way of life (Schrire, 1984; Wilmsen, 1989; Wilmsen and Denbow, 1990). This 'revisionist' view sees the foragers' simple technology, nomadism and sharing of food as part of a culture of poverty generated by the larger political economy and not as institutions generated by the demands of foraging life. (There is a large and growing literature on both sides of this issue known in recent years as 'the Kalahari Debate'. Readers interested in pursuing this issue should begin with Barnard [1992a]).

While recognizing that many foraging peoples have suffered at the hands of more powerful neighbours and colonizers, *The Cambridge Encyclopedia of Hunters and Gatherers* challenges the view that recent hunter-gatherers are simply victims of colonial forces. Autonomy and dependency are a continuum, not an either/or proposition, and as John Bodley documents (*Cambridge Encyclopedia of Hunters and Gatherers*), despite the damage brought by colonialism, foragers persist and show a surprising resilience. Foragers may persist for a variety of reasons. As illustrated by the example of the Kalahari San of southern Africa, where much of the debate has focused, some San *did* become early subordinates of Bantu-speaking overlords, but many others maintained viable and independent hunter-gatherer lifeways into the 19th and 20th centuries (Solway and Lee, 1990; Guenther, 1993, 1998; Kent, 1996a; Robertshaw, *Cambridge Encyclopedia of Hunters and Gatherers*). Archaeological evidence reviewed by Sadr (1997) strongly supports the position that a number of San peoples maintained a classic Later Stone Age tool kit and a hunting and gathering lifeway into the late 19th century. When Ju/'hoan San people themselves are asked to reflect on their own history they insist that, prior to the arrival of the Europeans in the latter part of the 19th century, they lived as hunters on their own, without cattle, while maintaining links of trade to the wider world (Smith and Lee, 1997).

The general point to be made is that outside links do not automatically make hunter-gatherers subordinate to the will of their trading partners. Exchange is a universal aspect of human culture; all peoples at all times have traded. In the case of recent foragers, trading relations may in fact have allowed foraging peoples to maintain a degree of autonomy and continue to practise a way of life that they valued (Peterson, 1991, 1993).

Another case in point is exemplified by the Toba of the western Argentinian Gran Chaco. Gastón Gordillo (*Cambridge Encyclopedia of Hunters and Gatherers*) notes how the foraging Toba have maintained their base in the Pilcomayo marshes as a partial haven against direct exploitation. As the Toba say, 'At least we have the bush,' seeing their Pilcomayo territory as a refuge to come home to after their annual trips to the plantations to earn necessary cash. The view of the 'bush' as a refuge seems to be a common theme among many hunter-gatherers. What it brings home is that foragers believe in their way of life: foraging for them is a positive choice, not just a result of exclusion by the wider society.

To the contrary, the authors of this book, led by Lakota anthropologist Beatrice Medicine in the Foreword, question whether victimhood at the hands of more powerful peoples is the only or even the main issue of interest about hunters and gatherers. The authors start from the position that the first priority is to represent the life-worlds of contemporary hunter-gatherers faithfully. This invariably includes documenting the peoples' sense of themselves as having a collective history as hunter-gatherers. Whether this foraging represents a primary or secondary adaptation, it often continues because that way of life has meaning for its practitioners. It seems unwise, if not patronizing, to assume that all foragers are primarily so because they were forced into it by poverty or oppression.

It is more illuminating to understand hunter-gatherer history and culture as the product of a complex triple dynamic: part of their culture needs to be understood in terms of the dynamic of the foraging way of life itself, part from the dynamic of their interaction with (often more powerful) non-foraging neighbours, and part from the dynamic of their interaction with the dominant state administrative structures (cf. Leacock and Lee, 1982).

A Brief History of Hunter-gatherer Studies

If a single long-term trend can be discerned in hunter-gatherer studies it is this: studies began with a vast gulf between observers and observed. 18th- and 19th-century treatises on the subject objectified the hunters and treated them as external objects of scrutiny. With the development of field anthropology, observers began to know the foragers as people and the boundaries between observers and observed began to break down. Finally in the most recent period, the production of knowledge has become a two-way process; the role of observer has begun to merge with the role of advocate and the field of hunter-gatherer studies has come to be increasingly influenced by agendas set by the hunter-gatherers themselves (Lee, 1992).

The more formal history of hunter-gatherer studies parallels the history of the discipline of anthropology. The peoples who much later were to become known as 'hunters and gatherers' have been an important element in central debates of European social and political thought from the 16th century forward (Barnes, 1937; Barnes and Becker, 1938; Meek, 1976). As described in the chapter by Alan Barnard (*Cambridge Encyclopedia of Hunters and Gatherers*, Part II), philosophers from Hobbes, Locke and Rousseau onward have drawn upon contemporary accounts of 'savages' as a starting point for speculations about life in the state of nature and what constitutes the good society.

These constructions became more detailed as more information accumulated from travellers' accounts, resulting in elaborate schemes for human social evolution in the works of the 18th-century Scottish Enlightenment – Smith, Millar and Ferguson – as well as on the continent – Diderot, Vico and Voltaire (Barnes, 1937; Harris, 1968).

Well before the 1859 publication of Darwin's *On the Origin of Species* the question of the antiquity of humanity became a central preoccupation of scholars, initiated in part by John Frere's famous 1800 essay which made the then heretical suggestion that teardrop-shaped, worked-stone objects found buried in river gravels at Hoxne, Suffolk, UK in association with extinct mammals may indeed not have been Zeus' thunderbolts, but instead implements made by humans that could be traced 'to a very distant period, far more remote in time than the modern world' (quoted in Boule and Vallois 1957, p11).

With the rise of European imperialism and the conquest of new lands came the beginnings of anthropology as a formal discipline. In the academic division of labour, while sociologists adopted as their mandate understanding urban society of the Western metropole, anthropologists took on the rest of the world: classifying diverse humanity and theorizing about its origins and present condition. The 19th-century classical evolutionists erected elaborate schemes correlating social forms, kinship and marriage with mental development and levels of technology. The world's hunters were usually relegated to the bottom levels. In Lewis Henry Morgan's tripartite scheme, of 'Savagery, Barbarism, and Civilization', hunters were either Lower or Middle Savages, depending on the absence or presence of the bow and arrow (Morgan, 1877).

William Sollas was one of the first to define hunting and gathering as a specific lifeway, and in *Ancient Hunters and their Modern Representatives* (1911) he linked ethnographies of recent hunters with their putative archaeological analogues. Modern Eskimo resembled Magdalenians, African Bushmen stood in for Aurignacians, and so on.

Essential to the development of modern anthropology was the decisive repudiation of the classical evolutionary schemes and their implicit (and often explicit) racism. Franz Boas' watershed study *Race, Language and Culture* (1948) demonstrated that the three core factors varied independently. A 'simple' technology could be associated with a complex cosmology, members of one 'race' could show a wide range of cultural achievements, and all languages possessed the capacity for conveying abstract thought. It was only on the twin foundations of Boasian cultural relativism and the emphasis on fieldwork that modern social and cultural anthropology could develop.

It is striking that most of the founders of the discipline both in North America and in Europe carried out landmark studies of hunters and gatherers. Boas himself went to the Canadian Arctic in 1886 as a physical geographer (his doctoral dissertation was on the colour of sea water), but his ethnographic study of the Central Eskimo (1888) became one of the seminal works in American anthropology. He went on to carry out decades of research with the KwaKwaKa'wakw (Kwakiutl) on the North-west Coast of British Columbia, a classic example of a *complex* hunter-gatherer group (Boas, 1966). Boas' close associates A. L. Kroeber and Robert Lowie also established their reputations through major research on hunting and gathering peoples, Californian and Crow Indians respectively (Kroeber, 1925; Lowie, 1935).

Founders of British anthropology shared a similar early focus, beginning with A. R. Radcliffe-Brown's study of the Andaman Islanders in 1906–1908 (1922). The great Bronislaw Malinowski, before going to the Trobriand Islands, wrote his doctoral dissertation on the family among the Australian Aborigines (1913). In France, while neither did hunter-gatherer fieldwork, both Emile Durkheim and Marcel Mauss carried out intensive library research on foraging peoples, with the former writing about Australian aboriginal religion in *Elementary Forms of the Religious Life* (Durkheim, 1912) and the latter writing his seminal essay on the seasonal life of the Eskimo (Mauss, 1906). Two decades later Claude Lévi-Strauss began his distinguished career with a 1930s field study of the hunting and gathering Nambicuara in the Brazilian Mato Grosso, before returning to Paris to write his influential works on the origins of kinship and mythology (1949, 1962a, 1962b, 1987).

Mention should also be made of the 1898 British expedition, led by A. C. Haddon, to the Torres Strait Islanders with their affinities to the Australian Aborigines, of the American Museum of Natural History's Jesup North Pacific Expedition to Siberia in 1897 (see Grant, 1995), and of the brilliant series of expeditions by Danish anthropologists to Greenland and the Canadian Arctic led by Mattiessen and Rasmussen. Important research traditions can also be discerned in Australia and Russia.

Modern studies of hunting and gathering peoples can be traced arguably to two landmark studies of the 1930s. First is the 1936 essay by Julian Steward who, in a *festschrift* for his mentor, A. L. Kroeber, wrote on 'The social and economic basis of primitive bands' (1936). After four decades of scholarly emphasis on careful description without theory building, Steward sought to revive an interest in placing hunter-gatherer studies in a broader theoretical framework. Steward argued that resource exploitation determined to a significant extent the shape and dynamics of band organization and this ecological approach became one of the two foundations of hunter-gatherer studies for the next 30 years.

The second base was the classic essay by Radcliffe-Brown on Australian Aboriginal social organization (1930–1931). The peripatetic R-B had begun his career in South Africa and from there moved to Sydney, São Paulo and Chicago before taking up the chair in social anthropology at Oxford. During his Australian tenure he wrote a series of influential overviews of Aboriginal social organization. But unlike Steward, for whom *ecological* factors were paramount, R-B saw structural factors of *kinship* as primary. Australian Aboriginal societies were usually divided into moieties, and these dual divisions were often subdivided into four sections or eight subsections. These divisions had profound effects on marriage patterns, producing an intricate and elegant algebra of prescriptive alliances between intermarrying groups. Radcliffe-Brown was far less interested than Steward in what the Aborigines did for a living. While the clan and section membership ruled the kinship universe and nominally held the land, it was the more informal *horde*, a band-like entity, whose members lived together on a daily basis and shouldered the tasks of subsistence.

In the 1940s Radcliffe-Brown's kinship models were taken up by Lévi-Strauss, who placed Australian Aboriginal moieties at the centre of his monumental work *Les Structures élémentaires de la parenté* (1949). It is worthy of note that theories of band organization have continued to be dominated by these two alternative paradigms: an ecological or adaptationist approach which relies on material factors to account for forager social life, and a structural approach which sees kinship, marriage and other such social factors as the primary determinants. The two approaches are by no means incompatible, and although the two tendencies are still discernible in hunter-gatherer studies, many analysts have posited a dialectic of social and ecological forces in the dynamics of forager life (see Sahlins, 1972; Lee, 1979; Leacock, 1982; Peterson, 1991, 1993 and others).

The Man the Hunter Conference

In 1965, Sol Tax announced the convening of a conference on 'Man the Hunter' at the University of Chicago; the conference, organized by Irven DeVore and Richard Lee, took place 6–8 April 1966 and proved to be the starting point of a new era of systematic research on hunting and gathering peoples. One commentator called the Man the Hunter conference 'the century's watershed for knowledge about hunter-gatherers' (Kelly, 1995, p14). Present at the conference were representatives of many of the major constituencies in the field of hunter-gatherer studies (though no hunter-gatherers themselves), including proponents of the *ecological* and *structural* schools. There were critics of the late Radcliffe-Brown's theories as well as supporters; there were archaeologists, demographers and physical anthropologists, reflecting the revival of interest in evolutionary approaches then current in American anthropology. Among the key findings of the Man the Hunter conference were the papers focusing on the relative ease of foraging subsistence, epitomized in Marshall Sahlins' famous 'Notes on the original affluent society' (1968). Gender and the importance of women's work was a second key theme of the conference. The name 'Man the Hunter' was a misnomer since among tropical foragers plant foods, produced largely by women, were the dominant source of subsistence.

After Man the Hunter

A burst of research activity followed the convening of Man the Hunter and the publication of the book of the same title (Lee and DeVore, 1968). Scholars present at the conference brought out their own monographs and edited volumes (Damas, 1969; Balikci, 1970; Bicchieri, 1972; Sahlins, 1972; Watanabe, 1973; Marshall, 1976; Binford, 1978; Lee, 1979; Laughlin, 1980; Helm, 1981; Suttles, 1990).

The field of hunter-gatherer studies has always been a fractious one and consensus is rarely achieved. After 1968 new work critiqued key theses from Man the Hunter. The irony of the mistitle was not lost on feminist anthropologists who produced a series of articles and books with the counter theme of 'Woman the Gatherer' (Slocum, 1975; Hiatt, 1978; Dahlberg, 1981). The feminist critics were certainly taking issue with the concept of Man the Hunter, and not necessarily with the book's content since the latter had gone a long way toward re-establishing the importance of women's work and women's roles in hunter-gatherer society. This last point was taken up in detail by Adrienne Zihlman and Nancy Tanner in an important article which drew upon the evidence assembled in Man the Hunter to place 'woman the gatherer' at the centre of human evolution (Tanner and Zihlman, 1976).

At the same time a counter-counter-discourse developed among scholars who questioned whether women's subsistence contribution had been *overestimated*, and several cross-cultural studies were produced to argue this view, summarized in Kelly (1995, pp261–292). A related development was the discovery that women in hunter-gatherer societies do hunt, the most famous case being that of the Agta of the Philippines.

Original 'affluence' came in for much discussion and critique, with a long series of debates over the definition of affluence and whether it applied to all hunters and gatherers at all times or even to all the !Kung (Hawkes and O'Connell, 1981, 1985; Koyama and Thomas, 1981; Altman, 1984, 1987; Hill et al, 1985; Bird-David, 1992; Kelly, 1995, pp15–23). Seeking to rehabilitate the concept, Binford (1978) and Cohen (1977) addressed some of these issues, while James Woodburn's introduction of the distinction between immediate- and delayed-return societies (1982) helped to account for some of the variability in the level of work effort among hunter-gatherers.

A major development in hunter-gatherer research was stimulated by this debate. Struck by the often imprecise data on which arguments about affluence (or its absence) had been based, a group of younger scholars resolved to do better. They adopted from biology models about *optimal foraging* (Charnov, 1976) and attempted to apply these rigorously to the actual foraging behaviours observed among the shrinking number of foraging peoples where it was still possible to observe actual hunting and gathering subsistence. Important work in this area was carried out by a close-knit group of scholars, often collaborating, and variously influenced by sociobiology and other neo-Darwinian approaches: Bailey (1991), Blurton Jones (1983), Hawkes (Hawkes, Hill, and O'Connell, 1982; Hawkes, O'Connell and Blurton Jones, 1989), Hewlett (1991), Hill and Hurtado (1995), Hurtado (Hurtado and Hill, 1990), Kaplan (Kaplan and Hill, 1985), O'Connell (O'Connell and Hawkes, 1981), Eric Smith (1983, 1991), and Winterhalder (1983, 1986). Reviews and summaries of Optimal Foraging Theory are found in Winterhalder and Smith (1981), Smith and Winterhalder (1992), Bettinger (1991) and Kelly (1995). For critiques see Ingold (1992) and Martin (1983).

More classically oriented research on hunter-gatherers attempted to bring together much of the rich historical and ethnographic material that had accumulated since the 1940s. *The Handbook of North American Indians*, under the general editorship of William Sturtevant, chronicled the 500 Nations of the continent in a series of landmark regional volumes. Six of these deal largely if not exclusively with hunting and gathering peoples: *Northwest Coast*, edited by Wayne Suttles (1990); *Subarctic*, edited by June Helm (1981); *The Great Basin*, edited by Warren D'Azevedo (1986); *California*, edited by Robert Heizer (1978); *Arctic*, edited by David Damas (1984); and *Northeast*, edited by Bruce Trigger (1978) (see also Trigger and Washburn 1996). On other continents Barnard (1992b) and Edwards (1987) produced overview volumes on the Khoisan peoples and Aboriginal Australians respectively.

A New Generation of Research

While the optimal foraging researchers based their work on models from biology and the natural sciences, a larger cohort of hunter-gatherer specialists were moving in quite different directions. Drawing on symbolic, interpretive and historical frameworks this group of scholars grounded their studies in the lived experience of foragers and post-foragers seen as encapsulated minorities within nation states, who still strongly adhered to traditional cosmologies and lifeways. Examples include Diane Bell's *Daughters of the Dreaming* (1983), Hugh Brody's *Maps and Dreams* (1981), Julie Cruikshank's *Life Lived like a Story* (1990), Fred Myers' *Pintupi*

Country, Pintupi Self (1986), Elizabeth Povinelli's *Labor's Lot* (1993), and Marjorie Shostak's *Nisa: The Life and Words of a !Kung Woman* (1981).

The Conferences on Hunting and Gathering Societies (CHAGS)

One way of tracking broader trends in hunter-gatherer research is to follow the CHAGS series of conferences through the 1970s, 1980s and 1990s. In 1978 Maurice Godelier convened a Conference on Hunting and Gathering Societies in Paris to observe the tenth anniversary of the publication of *Man the Hunter*. The conference brought together scholars from a dozen countries including the Dean of the Faculty of the University of Yakutia, himself an indigenous Siberian (Leacock and Lee 1982). The conference proved such a success that Laval University offered to host a follow-up conference in Quebec in 1980. Organized by Bernard Saladin d'Anglure and Bernard Arcand, the conference continued the tradition begun in Paris, wherein anyone who wanted to participate could do so as long as they were self-financing. Inuit broadcasters were among the several members of hunter-gatherer societies present.

By now it was becoming clear that a need existed for continuing the series, and Professor I. Eibl-Eibesfeldt of the Max Planck Institute in the Federal Republic of Germany took on the task of organizing CHAGS III. The Munich CHAGS in 1983 was a smaller, by-invitation affair, and the book that resulted reflected one particular school (revisionist) of hunter-gatherer studies (Schrire, 1984). CHAGS IV, held at the London School of Economics in September 1986, returned to the more open policy with a wide range of constituencies represented. The active British organizing committee led by James Woodburn and Tim Ingold along with Alan Barnard, Barbara Bender, Brian Morris and David Riches produced two strong thematically organized volumes of papers from the conference (Ingold et al, 1988a, 1988b).

CHAGS then moved to Australia. Hosted by Les Hiatt of Sydney University, CHAGS V convened in Darwin, capital of the Northern Territory, in August 1988. CHAGS V proved to be a marvellous world showcase for the active community of anthropologists, Aboriginal people, and activists working on indigenous issues in Australia.

Fairbanks, Alaska was the location of CHAGS VI (1990), the first of the CHAGS series to be held in the US since the original 1966 Chicago conference. Convened by the late Linda Ellanna, the Fairbanks conference was memorable for being the first CHAGS at which a large delegation of Russian anthropologists was present, flying in from Provedinya just across the Bering Straits in Chukotka. Indigenous Alaskans played a prominent role in Fairbanks as well (Burch and Ellanna, 1994). CHAGS VII, in Moscow in August 1993, convened by Valeriy Tischkov and organized by Victor Shnirelman at the Russian Academy of Sciences, is discussed below. The international hunter-gatherer community convened for CHAGS VIII, at the National Museum of Ethnology in Osaka, Japan, in October, 1998, with future meetings projected in the new millennium for Scotland, India and southern Africa.

This ongoing series of CHAGS gatherings held on four continents has provided an excellent monitor on the state of hunter-gatherer research in recent decades, and a unique perspective on its increasingly international and cosmopolitan outlook.

While the theoretical debates of the Man the Hunter conference of 1966 had revolved around issues of the evolution of human behaviour, the recent series has moved relatively far from evolutionary and ecological preoccupations. In their stead hunter-gatherer specialists have developed several major foci of inquiry.

At the Moscow CHAGS in August 1993 and at Osaka, 1998, a large and active scholarly contingent focused on foragers in relation to the state; papers on land rights, court battles, bureaucratic domination and media representations documented the struggles of foragers and former foragers for viability and cultural identity in the era of Late Capitalism. Many of the research problematics grew out of close consultation with members of the societies in question. Increasingly it is they who are setting research agendas, and in some cases – Aleuts at Fairbanks, Evenkis at Moscow and Ainu at Osaka – presenting the actual papers. This branch of hunter-gatherer studies is closely aligned with the emerging worldwide movement for recognition of the significance of 'indigenous peoples' and their rights.

The humanistic wing of hunter-gatherer studies has been represented by a major focus at the recent CHAGS on symbolic and spiritual aspects of hunter-gatherer life. Here were found richly textured accounts of forms of consciousness, cosmology and ritual, while other papers dealt with the changing worldviews of foragers under the impact of ideologies of state and marketplace. To showcase the offering of the Moscow CHAGS there is an excellent volume of papers edited by Biesele et al (1999), with an equally rich set of publications planned for Osaka.

One theme unifying these diverse scholars from many countries was that all were able to see in hunter-gatherer society *some* component of historical autonomy and distinctiveness. The notion of 'pristine' hunter-gatherer was nowhere in sight, but neither did anyone argue that the cultural practices or cosmological beliefs observed were simply refractions of dominant outsiders, Soviet or Western. Refreshingly, the 'other's' reality was not considered to be so alien that the ethnographer was incapable of representing it with some coherence.

Another unifying theme was the recognition that change was accelerating, and that the magnitude of the problems faced by these indigenous peoples was enormous, especially those in the Russian North, for whom ecologically destructive socialist industrialization has been followed directly by the advent of get-rich-quick capitalism. Similar conditions were replicated in most of the world's regions where foragers persist.

Hunter-gatherer Studies Today

As humankind approaches the millennium, what are some of the main currents in research about hunter-gatherers, present, past and future? Four principal tendencies can be discerned. These are set out below with two provisos: first, none of these approaches has a monopoly on 'the truth'; each has something to offer and each has its shortcomings. Second, none in practice is air-tight, and many scholars may participate in two or more.

1. *Classic.* The internal dynamics of hunter-gatherer society and ecology continue to interest many scholars. Kinship, social organization, land use, trade, material culture and cosmology provide an ongoing source of ideas, models and analogies for archaeologists and others reconstructing the past. When due account is taken of the historical circumstances, ethnographic analogies can be a valuable tool. Archaeologists are now arguably the largest 'consumers' (and producers) of research on hunting and gathering peoples, even though the opportunities for basic ethnographic research are shrinking rapidly. Robert Kelly's book *The Foraging Spectrum* (1995) is an excellent example of work in the classic tradition (with a minor in behavioural ecology). Tim Ingold has authored several works which sought to integrate the social and the ecological through an application of neo-Marxist theory (1986), and Ernest Burch Jr. continues to produce meticulous ethnographies on arctic Alaska and Canada in the classic tradition (e.g. Burch, 1998). Theorists *beyond* anthropology continue to turn to the hunter-gatherer evidence in constructing their own models about economics or gender roles or cosmology or many other subjects where a basic human substrate is sought. The results are highly variable.
2. *Adaptationist.* Discussed above, the second 'tendency' is the area of behavioural ecology and Optimal Foraging Theory, with a strong presence in the US, particularly at the Universities of Utah and New Mexico. The adaptationists are the prime advocates of a strictly 'scientific' paradigm within hunter-gatherer studies and this places them, to a degree, at odds with others in the field for whom humanistic and political economic approaches are primary (cf. Lee, 1992). While some behavioural ecologists approach issues of demography and subsistence from a historically contextualized position, a significant number continue to march under the banner of neo-Darwinian sociobiology. And while some acknowledge the impact of outside forces – such as dam construction, logging, mining, rainforest destruction, bureaucracies, missionaries and land alienation – on the people they study, others focus narrowly on quantitative models of foraging behaviours as if these existed in isolation. In addition to criticizing their science, critics of this school have argued that by treating foragers primarily as raw material for model building, the behavioural ecologists fail to acknowledge foragers' humanity and agency, as conscious actors living through tough times and facing the same challenges as the rest of the planet's beleaguered inhabitants. Having fought to maintain their scientific rigour as

anthropology-at-large moves in a more humanistic direction, the challenge for the behavioural ecologists now is to make their work also relevant and useful to their subjects in their fight for cultural, economic and ecological survival. Within the field of behavioural ecology of hunter-gatherers, and in relation to the terms of this field, Kristen Hawkes has been the most articulate spokesperson, while Hill and Hurtado (1995) and Smith and Winterhalder (1992) offer some of the best recent work.

3. *Revisionist*. This school of thought argues that the peoples known as 'hunter-gatherers' are something quite different: primarily ragged remnants of past ways of life largely transformed by subordination to stronger peoples and the steamroller of modernity. Two of the principal authors of this view are Schrire (1984) and Wilmsen (1989). Although the evidence presented in this volume challenges this thesis at a fundamental level, the 'revisionists' do raise serious questions. For too long students of hunter-gatherers and other pre-state societies tended to treat in isolation the peoples they researched, regarding them as unmediated visions of the past. Today history looms much larger in these studies. Hunter-gatherers arrive at their present condition by a variety of pathways. By acknowledging this fact and being sensitive to the impact of the wider political economy, the authors of this volume are responding to the challenges made by the revisionists. Beside the archaeological and historical evidence contra the revisionist position, the most eloquent testimony in the revisionist debate is the voices of the people, setting out their ongoing sense of themselves as *historically rooted* peoples with a tradition and identity as hunters and gatherers. Their eloquence, resilience and strength demonstrate that even in this hardbitten age of 'globalization' other ways of being are possible.
4. *Indigenist*. This fourth perspective brings the people studied, their goals and aspirations, firmly into the centre of the scholarly equation. For many of the authors in this book the indigenist perspective represents the outcome of a long search for an anthropology of engagement that is also scientifically responsible. The long revolution in the ethics of anthropology has come to the present conjuncture in which the still-legitimate goals of careful scholarship must he situated *in tandem with ethical responsibilities* to the subjects of inquiry. This involves at the very least attempting to account for the forces impacting on peoples' lives in ways that valorize their choices and give them useful tools to work with.

For example, in the volume *Cash, Commoditization, and Changing Foragers* (1991), co-edited with Toshio Matsuyama, Nicolas Peterson offers a coherent framework for understanding the complex impacts of the market economy on the internal dynamics of foraging peoples. This issue has tended to polarize the field of hunter-gatherer studies into two camps: the revisionists who see capitalism as having long ago destroyed the foraging economy, and the 'pristinists' who deny or minimize these effects. Peterson's subtle and insightful analysis succeeds in bridging these two entrenched positions and showing areas of common ground. The market and the welfare state, in Peterson's view, have altered but not destroyed foraging economies; in many cases the impacts have been absorbed and put to use in reproducing forager communities and identity *within* the wider society. A similarly lucid and original analysis underlies Peterson's re-analysis of the subject of sharing and gift-giving (1993). He focuses on the ways in which sharing reproduces core values within foraging communities, enabling them to maintain independent identity in spite of the vastly greater power and reach of the enveloping market-based society.

Researchers in the indigenist perspective must perform a difficult balancing act: how to combine advocacy and good rigorous scholarship, without subsuming ethical obligations of the scholar to political expediency (or vice versa).

In addition to a number of authors in this volume, the 'indigenist' perspective on hunter-gatherers is evident in the work of such scholars as Eugene Hunn (1990), Joe Jorgensen (1990), Basil Sansom (1980), Janet Siskind (1980) and Polly Wiessner (1982).

Given the growing political visibility of modern foragers within their respective nationstates and the worldwide movement for indigenous rights, recent research has been based increasingly on agendas arising from within the communities themselves. Land claims, social disintegration, substance abuse and the concomitant movements to reconstitute 'traditional' culture and revitalize institutions have become central concerns.

About the *Cambridge Encyclopedia of Hunters and Gatherers*

Part I is arranged into seven sections, based on the world's principal geographical regions. Each is introduced by an overview of the region's foraging peoples by the regional editor, followed by an essay on the area's prehistory. The heart of the *Encyclopedia* is the individual case studies of the history, ethnography and current status of over 50 of the world's best-documented hunter-gatherer groups. The goal here is to present a balanced account that includes both the traditional culture and social forms, and the contemporary circumstances and organization for resistance. Authors were chosen not only for their expertise as authorities but also for the contributions they have made as advocates for the well-being of the people they write about. Each chapter also contains a sidebar in which members of the society speak to the reader in direct quotations.

Part II contains thematic essays covering a broad array of topics: from mythology, religion, nutrition, gender and social life, to experience at the hands of colonial forces and status in contemporary states and human rights. Other essays address the traditional and contemporary music of hunter-gatherers on the 'World-beat' scene, and their current position in world art markets where works by aboriginal artists may fetch four and five figures. These essays thus situate the hunting and gathering peoples not only in their own world but also in the wider world's political economy and the emerging global culture.

The Regions

1 North America (regional editor: Harvey A. Feit; archaeological background: Aubrey Cannon)

Prior to colonization about two-thirds of North America was occupied by hunters and gatherers, including most of what is now Canada and much of the US west of the Mississippi. Some of the best-known recent foragers reported in the *Encyclopedia* include the James Bay Cree (Feit) and Labrador Innu (Mailhot), the Subarctic Dene in western Canada and Alaska (Asch and Smith), and the Inuit (Eskimo) of Arctic Canada (Burch and Csonka) and Alaska (Worl). The foragers of the Great Basin are represented by the Timbisha Shoshone of Nevada (Fowler). The mounted hunters of the Plains and intermontane West represent a successful secondary adaptation to big-game hunting by former farmers and foragers after the arrival of the horse in the 17th century (Kehoe). Complex foraging societies, with slavery and rank distinctions, occupied all of the west coast of North America from California to the Alaskan panhandle (Daly).

2 South America (regional editor: Laura M. Rival; archaeological background: Anna C. Roosevelt)

The southern cone of the South American continent was occupied by foragers including, at the extreme south, the Ona, Yamana and Selknam of Tierra del Fuego (Vidal) and the Toba of the western Chaco (Gordillo). Some of the hunters of the southern cone became mounted hunters with the arrival of the horse, paralleling processes in North America. The numerous peoples of the Amazon and Orinoco basins combined foraging with shifting horticulture, with some like the Equadorean Huaorani (Rival) relying largely, and a few peoples like the Cuiva of Venezuela (Arcand) almost entirely, on foraging. South American foragers like the Sirionó (Balée) show evidence of having been more reliant on farming in the past. The Paraguayan Aché (Hill and Hurtado) are well known in anthropological circles for the detailed behavioural ecological studies made about them.

3 North Eurasia (regional editors: Victor A. Shnirelman and David G. Anderson, with Bruce Grant; archaeological background: Victor A. Shnirelman)

In northern Siberia and the Russian Far East a number of hunter-gatherer groups exist, combining foraging with small-scale reindeer herding. These groups vary widely in the timing of colonial encounter (some being reached only in the late 19th century), and in the degree to which they have suffered from the industrialization of the Soviet period. Notable among those who were primarily foragers are the Khanti (Nemysova, with Bartels and Bartels), Nia/Nganasan (Golovnev), Iukagir (Ivanov), Ket (Alekseenko), and the Chukchi and Siberian Yupik (Schweitzer), the latter close relatives of the Alaskan Eskimo. The Evenki of central Siberia (Anderson) and the Nivkh of Sakhalin Island (Grant) have been particularly hard hit by industrial pollution and the break-up of the Soviet Union. In addition Svensson discusses the well-known Ainu culture of Hokkaido, Sakhalin and the Kurile Islands.

4 Africa (regional editor: Robert K. Hitchcock; archaeological background: Peter Robertshaw)

Although most of the continent pre-colonially was occupied by farmers, herders and agrarian states, Africa was home to several well-known foraging peoples. The Pygmies occupy the equatorial rainforest in a broad belt across central Africa from Cameroon to Rwanda, represented in the volume by the Mbuti of the Congolese Ituri Forest (Ichikawa) and the Aka of the Central African Republic (Bahuchet). In East Africa the Hadza of Tanzania (Kaare and Woodburn) have remained staunchly independent of neighbouring farmer-herders, while the Okiek of Kenya (Kratz) have long-established trade relations with the Maasai. In the Kalahari Desert of Botswana, Namibia and Angola live the well-known San or Bushmen peoples. Some, like the Ju/'hoansi (Biesele and Kxao Royal-/O/oo) and the central Kalahari/Gui of Botswana (Tanaka and Sugawara), remained relatively autonomous until recently; others like the Tyua of eastern Botswana (Hitchcock) have a long history of close contact. The Mikea of south-eastern Madagascar became foragers in the 19th century, adopting the relative security of forest hunting and gathering during a period of instability and warfare (Kelly et al).

5 South Asia (regional editor: Nurit Bird-David; archaeological background: Kathleen Morrison)

In this region of ancient civilizations a surprising number of foragers exist, occupying upland forested areas and providing forest products (honey, medicinal herbs, furs) to lowland markets. It is this economic niche presumably that has allowed the South Asian hunter-gatherers to persist to the present and remain viable. Examples include the Wanniyala-aetto (Veddah) of Sri Lanka (Stegeborn), the Nayaka of Kerala (Bird-David), the Paliyan (Gardner), and the Hill Pandaram (Morris) in the southern tip of the subcontinent, and the Birhor (Adhikary) and Chenchu (Turin) in central and eastern India. Most famous are the Andamanese, occupying a series of islands in the Bay of Bengal, who remained isolated into the late 19th century and in one case well into the 20th (Pandya).

6 South-east Asia (regional editor: Kirk Endicott; archaeological background: Peter Bellwood)

Orang Asli is a cover term for the indigenous non-agricultural peoples of the Malay peninsula and insular South-east Asia. Among the best known are the Batek (Endicott) and Jahai (Van der Sluys) in the Malaysian forest and the Batak (Eder) on the Philippine island of Palawan. Other groups are found in Thailand, Myanmar, Laos and China's Yunnan province (Song and Shen). On the island of Borneo live the Penan of Sarawak (Brosius), firmly rooted in hunting and gathering until recent displacement by multinational logging interests. The Philippine main islands have several pockets of foraging peoples, including the Agta of northeastern Luzon famous for their female hunters (Griffin and Griffin).

7 Australia (regional editor: Nicolas Peterson; archaeological background: Michael A. Smith)

Prior to European colonization in the late 18th century, Australia was entirely occupied by hunting and gathering peoples. These suffered a precipitous decline after 1788. Nevertheless in the centre, north and west, Aboriginal people have persisted, the last nomadic Pintupi foragers in the Western Desert coming in to settlements in the 1950s and 1960s (Myers). Arnhem Land Aborigines such as the Yolngu (Keen) retain significant elements of social and ritual organization, as do some of the desert groups like the Warlpiri (Dussart), Pintupi (Myers), and Arrernte (Arunta) (Morton). The Aborigines of Cape York in north-east Queensland (Martin) and the Kimberleys (Toussaint) and the famous Tiwi of Bathurst and Melville Islands (Goodale) give a sense of the range of variation among contemporary Aboriginal peoples. A significant percentage of Aborigines are urbanized and, like the Ngarrindjeri in South Australia (Tonkinson), are struggling to preserve and revivify their cultures and land rights in the face of the indifference and tokenism of Australian society at large. The Torres Strait Islanders (Beckett) lie geographically and culturally midway between Australia and Papua New Guinea. They are active partners with Aborigines in political movements, legal challenges, and administrative structures.

Although the main story of hunters and gatherers today is carried by the 53 case studies and their regional introductions, important themes cross-cut the focus on regions and cultures. The special topic essays focus attention on broader issues involving or affecting hunting and gathering peoples worldwide.

Alan Barnard traces the complex perceptions (and misperceptions) of hunter-gatherers through Western intellectual history. As noted above, Barnard sensitizes us to the fact that foragers have always been viewed through a thick lens of ideology and this became even more pronounced when European colonialism and its oppositions became predominant sites of political and cultural discourse about foragers. Barnard documents how current debates are actually reprises of older controversies resurfacing anew.

Andrew Smith follows with a magisterial survey of the world prehistory of hunting and gathering peoples. Smith notes that for much of human history hunting and gathering was the universal mode of life. His overview offers a sense of the world-historical events that led first to the 2 million year ascendancy and then the eclipse of hunting and gathering as, continent by continent, farmers, herders and states arose, ultimately to marginalize and encapsulate the foraging world.

John Gowdy represents a refreshing incursion by a sister discipline to the world of hunter-gatherers. An economist, Gowdy makes good use of hunter-gatherer materials to take a sharp look at the conventional wisdom economists (and the rest of us) live by. Gowdy questions in turn the economic concepts of scarcity, production, distribution, ownership and capital and in each instance counterposes alternative examples from the hunter-gatherer literature. Following on Marshall Sahlins' pioneering work (1968, 1972), Gowdy portrays these economic core concepts more accurately as culturally bound constructions specific to a time and place and not eternal expression of basic human nature. These themes are developed in greater depth in Gowdy (1998).

For over 20 years Tim Ingold has been reflecting on hunting and gathering as a way of life, a mode of production and an ecological adaptation. Here he brings these lines of inquiry together to ponder the nature of hunter-gatherer sociality. Ingold asks whether hunter-gatherers, living in direct, face-to-face groupings, do not exhibit a form of sociality of a qualitatively different nature from that of the rest of humanity, living in hierarchical, often anonymous, often alienated circumstances. After reviewing theories of the patrilocal band and of 'primitive communism' Ingold then draws out some of the profound implications of this line of inquiry for social theory more generally.

The second group of special essays surveys six major aspects of hunter-gatherer life in cross-cultural perspective. Karen Endicott addresses the large ethnographic and critical literature about gender in hunting and gathering societies. Noting the persistent male bias of older ethnographies that pushed women to the margins, Endicott discusses a number of recent studies that rectify this misperception. Women's roles in subsistence, kinship and politics are explored. Drawing on her own familiarity with South-east Asian foragers, Endicott considers the well-known views of Eleanor Leacock about women in foraging societies (1978, 1982) in opposing the doctrine of universal female subordination.

Catherine Fowler and Nancy Turner discuss Traditional Ecological Knowledge (TEK). Hunter-gatherers are notable for the intensity of their spirituality and connection to the land, a connection further intensified by the experience of dispossession. Fowler and Turner show how, among hunter-gatherers, systems in the natural world are incorporated into the spiritual and social worlds. 'Particularly important', in their view, 'is the sense of place and purpose communicated by the oral tradition, and the cumulative wisdom derived from knowledge of complex ecological relationships.' The authors point to the negative consequences of breaking this connection, leading to loss of purpose, language and culture. They also speak of groups in which the connection to land and foraging is being recaptured.

Mathias Guenther presents a rich account of the intellectual and spiritual world of hunter-gatherers, a vast continent of myth and practice that is a major world-historic heritage. While Fowler and Turner show how Nature is an encyclopedia of practical knowledge, Guenther views the cosmologies of foraging peoples as wellsprings of supernatural and ontological meanings. He explores the ubiquity of the Trickster figure in world mythology and traces the anthropological history of shamanism from its first documentation in eastern Siberia in the late 19th century to its recognition as a religious phenomenon found in every continent. Guenther also documents the successful adaptation of some shamanistic methods into healing practices of contemporary medicine.

In an original synthesis Victor Barac explores the world of hunter-gatherer music. Presenting examples from Africa, Australia and North America, Barac documents the core features of this genre and its points of difference from the musics of non-foraging peoples. He then gives an account of the extraordinary impact made by hunting and gathering musicians and singers upon the 'Worldbeat' and pop music scenes. In examples ranging from the Australian Aboriginal group Yothu Yindi to the Canadian Inuit artist Susan Aglukark, Barac documents the unique interweaving in the music of these artists of traditional elements along with profound reflections on contemporary themes of poverty, violence, racism and loss.

Howard Morphy follows with an overview of the art of hunting and gathering peoples. He first notes variation in artistic production and the wide variance in the permanence of this art – from body and sand painting which lasts a day to rock art lasting millennia. Morphy traces three cases of hunter-gatherer art which have reached world status: North-west Coast art, Aboriginal Australian bark paintings, and Inuit soapstone carvings. Each has enjoyed extraordinary success on international art markets, as well as becoming part of the iconography of their respective nationstates.

One of the recurrent themes in hunter-gatherer research is the surprisingly good nutritional status of foraging peoples. As S. Boyd Eaton and Stanley Eaton point out, there are many lessons to be learned from the study of foragers' diet and exercise regime. In the precolonial period foragers led healthy outdoor lives with a diet consisting entirely of 'natural' foods. Salt intake and refined carbohydrate consumption were low and obesity rare, as were many of the diseases associated with high-stress sedentary urban living such as diabetes, heart disease and stroke. While infectious diseases took their toll, some of these were evidently introduced during the colonial period well before the colonists themselves arrived in local areas.

One of the strangest episodes in the history of hunter-gatherer studies began in 1972 when a Philippine-American team reported finding a 'Stone Age people' who were claimed to have been living in caves on a diet of wild foods out of touch with the rest of the world for over 500 years! The Tasaday, as they came to be known, became world-famous, featured in international media and in several *National Geographic* specials. Despite the public's acceptance, nagging doubts remained among scholars about the authenticity of such a seemingly far-fetched story. Gerald Berreman traces the history of the Tasaday from the beginning and reveals it as an elaborate hoax, probably the biggest anthropological hoax since the Piltdown fraud. With painstaking detail Berreman invites the reader to evaluate the evidence in what has become a fascinating detective story of greed in high places and otherwise blameless indigenous people drawn in as accomplices.

John Bodley chronicles the complex history of the encounter between hunting and gathering peoples and European colonialism. In the 500 years of European incursions into the rest of the world, band and village societies faced insurmountable odds and many succumbed to a combination of military predation, land loss and the effects of introduced diseases. Yet despite the horrors of the colonial period, a surprising number of foragers survived and are present to witness the dawn of the third millennium. Bodley documents the tenacity and ingenuity of these survivors and how they combined resistance and accommodation to preserve a way of life they valued.

As long as they had the frontier, hunting and gathering peoples could survive by moving beyond the reach of the colonial authorities. But with the arrival of the modern nationstate, administrative structures reached everywhere. David Trigger surveys the ways in which states of the First, Second and Third Worlds first pacified and censused and then divided and ruled foraging peoples, attempting to make them conform to the role of 'good citizens'. Trigger offers important insights into the lived realities of foragers and post-foragers today as they adjust to bureaucratic domination. He notes significant differences between the situation of former foragers in the Western capitalist states, and those in the developing world and the former USSR.

In the last chapter, Robert Hitchcock surveys the state of human rights for indigenous peoples. Given their new status as 'wards' of states, foragers have undergone transformations in political consciousness. Foragers are increasingly coming to see themselves as encapsulated minorities, as ethnic groups, and as stakeholders within the civil societies of states. At a broader level they are coming to see themselves as part of the larger global community of indigenous peoples. Indigenous peoples now are a force on the world stage, but despite the UN's declaration of the period 1995–2004 as the 'Decade of Indigenous Peoples' the human rights of many continue to be abridged, violated and denied, Hitchcock surveys the complex terrain on which foragers and post-foragers make claims on the political agendas of states and international organizations. Hitchcock appends a useful up-to-date list of over 50 indigenous organizations and advocacy groups.

An Afterword

These 14 essays and the case studies that precede them convey a sense of what makes present-day hunters and gatherers so intriguing. Long the subject of myth and misconception, the hunting and gathering peoples have come into focus in recent years. Far from being simply the cast-offs of creation or victims of history, the foraging peoples have become political actors in their own right, mounting land claims cases, participating in the environmental movement, and lobbying for their rights with governments and the UN. Also they are being sought out by spiritual pilgrims from urban industrial societies seeking to recapture wholeness from an increasingly fragmented and alienated modernity.

As humanity marks the new millennium, there is an increasing preoccupation with where we have come from and where we are going. The accelerating pace of change and the ceaseless transformations brought about by economic forces have had the effect of obliterating history, creating a deepening spiritual malaise. For centuries philosophers have sought the answers to humanity's multiple problems in the search for the holy grail of 'natural man', the search for our ancestors. *The Cambridge Encyclopedia of Hunters and Gatherers* does not offer simple or pat answers to the questions of the social philosophers. Yet it is our hope that in the documentation of foragers' history, culture and current situation, readers will find a rich source of ideas, concepts and alternatives to fuel the political imagination.

Mind

H. Brody

1

In 1973, after a year in the Arctic, early one morning I visited Anaviapik's house in Pond Inlet. Anaviapik and Ulajuk were at their small kitchen table, drinking tea. Everyone else was asleep. I went in, helped myself to a mug and sat down with them. As always, they said how pleased they were to be visited. '*Pulartiarit*,' said Anaviapik, meaning literally 'Visit well,' 'Be welcome.' Then he asked: '*Isumassaqarpit*?' 'Do you have the material for thought?', meaning 'Is there something on your mind?' 'No,' I said. 'I'm just visiting.'

'That's good,' said Anaviapik, 'because I have a thought, and I have a question for you.'

His question, which seemed to arise from a conversation that he and Ulajuk had been having just before I came into their house, was this: '*Qanuingmat tassumanik Qallunaat isumaqattalaursimajuit Inunnit isumarqanigitunit iila isumarqijugut Inuulluta? Taima isumangmata tusaumavit?*' 'How is it that in the old days the Qallunaat always thought that the Inuit had no thoughts and that we Inuit were mindless? Is that what you have heard?'

As I thought about what to say, Ulajuk and Anaviapik smiled at me. Then both of them burst out laughing. I recognized their laughter as a way of removing any possible risk that they might sound aggressive. This was just a question, a puzzle, something they wanted to talk to me about.

2

In 1979, late in the year but before the snows had come, I arrived in Fort St. John to discover that Thomas Hunter, the Dunne-za elder, was in hospital. Thomas was now in his eighties, a small, tough man whose face had become a maze of wrinkles but whose hands were still strong and whose eyes were still bright with curiosity

Brody H. 2000. Mind. In *The Other Side of Eden*, reproduced with permission of A P Watt Ltd on behalf of H R Brody Ltd, and with permission of Faber and Faber, London.

and ideas. He had been ill for a while, coughing a great deal and suffering periods of sudden weakness.

A few weeks earlier, Thomas's family, along with several others, had moved from the Halfway River Reserve to a moose-hunting area a few miles to the north. There they had been preparing dry meat. Moose were plentiful, and the hunters had killed several. The meat had been brought back to the family tents for the women to slice into long, paper-thin sheets. They hung these on wooden frames beside fires, where the meat part dried and part smoked. After a few days, the slices were almost weightless and perfectly preserved. They were a source of concentrated protein that could be stored for many months and packed into bags that were easy to carry. Thomas had not gone to the dry-meat camp that year. He had become very weak; before the others left, he had been taken to the Fort St. John hospital.

I found him lying on his bed in a small public ward, dressed in jeans and a vest. As soon as he saw me, he said, as he had so often before when I arrived back in Dunne-za country: 'I know you here. Time to hunt. We better go someplace, look for moose.' I thought he was making a joke, then realized he was serious. 'But can you leave the hospital?' I asked. 'You see doctor,' said Thomas. 'Then we go to dry-meat camp.'

Thomas's English was fluent, but it came from his fur-trading days. He used it to make direct statements or to ask straightforward questions. His real language was Dunne-za Athabaskan. So we did not have a discussion about just how he was going to manage in the camp. He had made himself clear, and I went to find his doctor.

The doctor was a tall young man in a hurry. He said that Thomas was very sick. His lungs were 'gone'. I asked what the actual diagnosis was. 'TB,' he said. 'Maybe cancer as well.' He paused, then added: 'Nothing we can do.' So was it all right to take him out of the hospital? 'Fine,' said the doctor. 'I just hope that you take him somewhere he can get some care.' Were there medicines I should take with us? Was there any treatment he should come back to the hospital for? The doctor shrugged. 'There's nothing much anyone can do,' he said. 'He's old and his lungs are gone.' I could take Thomas whenever he wanted to go.

I was upset. There was a certain callousness about the way the diagnosis had been given, and something eerie about the lack of medical prescription. Was Thomas about to die? I went back to Thomas's bed and sat down beside him. He looked at me. He must have known that I had seen the doctor. He didn't say anything. I looked at his eyes, which seemed to have sunk back into his skull. He had lost weight. 'The doctor says you can leave here when you want. But I guess you could stay, too, if that seemed better.' I paused. 'You would be cared for here.'

Thomas did not hesitate. 'Okay we leave now?' 'Yes,' I said. 'When you want.'

'Now,' he said. He sat up on his bed, swung his legs over the side and stood up. We found his shoes and jacket and walked out.

Thomas wanted to go straight to the dry-meat camp. He did not say much, and I noticed that he was breathing with some difficulty. I was worried. Maybe we should go to the reserve, where he would have a bed and be within a few hundred yards of the clinic; at least we would have access to a phone. He could call for emergency help if he needed it, or see the nurse who came each week. No, said Thomas, he wanted to be in the camp.

When we got to the camp, everyone else was away. I asked Thomas again if he would like to go to the reserve, at least to find other members of his family. 'No,' he said. 'Better finish here.' He went to his family's tent and sat down at its entrance. He was tired and weak. I made a fire for him and put a kettle on to boil. I fetched a few pieces of dry meat so that he could eat whenever he was hungry. He sat very still, looking around, not saying much.

As the fire blazed up and the kettle began to steam, Thomas said: 'See the horses.' I looked up and saw that the family's horses were all standing close to the little group of tents. They had their heads low to the ground and seemed to be staring at us. I was astonished: the horses always kept their distance from the camp, moving far into the forest, doing their best not to be caught and ridden or loaded with packs. Every morning they had to be trailed into the woods and, often with some difficulty, herded back to the tents, where they could be tethered for use. Now they stood there, close, unmoving.

'Horses they know,' he said. 'In my mind.'

I waited for a while, making sure Thomas got his tea and was comfortable. The horses stayed there, watching. Thomas died a few weeks later.

3

In 1988, during the filming of *Hunters and Bombers*, we interviewed Mary Adele Andrew, the mother of Alex Andrew, my Innu guide and interpreter. She was a large, energetic woman who had brought up a big family as a single parent – her husband had died when the children were still young. She had a strong inner warmth, a generosity of spirit that insisted anyone who came to her house must sit and eat whatever she happened to be cooking. I had been with her at a summer camp, and I knew how much she loved to be far away from the settlement, out on the land. I knew she would have a great deal to say about what had happened to her family, and to all the Innu she knew, as a result of having spent so much time stuck in Sheshashiu.

Mary Adele sat at her kitchen table and talked to Alex. She spoke slowly, carefully, with great force. 'These houses were built to trap us,' she said. 'They told us, "Stay here, you'll get a house." But it was a trick to get our children to go to school and to make sure we stayed in one place. It was a lie, so we wouldn't see our land being destroyed. They hoped we wouldn't say anything. They said when our children leave school, they'll get good jobs. But nothing happened.'

Instead, the people had lost their real wealth, their real homes. Their land had been taken. The Church and the school, the priests and the government, had joined forces to do this. In one of our interviews, Elisabeth Penashue told us: 'In the old days we used to revere the priests. They were powerful and said, "Don't go out on the land. Send the kids to school or you will lose your family allowance." Parents were afraid. They made the children go to school. When a priest told us to do something, we did it. We listened to him as if he was Jesus.'

In defiance of these intense pressures, Mary Adele Andrew and Elisabeth Penashue, as well as some others, continued to spend as much time as they possibly could on their lands with their families. They were teaching the young how to live there, as Innu. It had been hard, and some had lost a great deal, but there was hope – so long as they could keep going onto the land.

One day at a summer camp, where the women were baking bread in ovens they had scooped out of sand heated with large fires of driftwood, Mary Adele said: 'On the land we are ourselves. In the settlement we are lost. That was the way they made our minds weak.'

4

European 'discovery' of the New World, those great adventures to the Americas as well as to southern Africa and Australasia, led to a set of theories about the peoples who lived in these lands. The theories, which disregarded hunter-gatherer economic systems, languages and belief, were underpinned by the idea that hunter-gatherers were not quite human beings at all.[1]

Articulate colonists of southern Africa in the 16th century declared that the Khoisan peoples they encountered at the Cape of Good Hope were 'the very reverse of humankind … so that if there's any medium between a rational animal and a beast, the Hotantot [*sic*] lays the fairest claim to that species.' In Australia, Aborigines were classified as being at a midpoint on the evolutionary ladder, more a species of animal than human. When William Lanney, the last Aborigine of Tasmania, died in 1869, a struggle to get possession of his bones was fuelled by the belief that 'he represented a last living link between man and ape'.

In 16th-century Spain, the question arose as to whether or not the original inhabitants of the colonies in the Americas were 'natural slaves'. The notion came from Aristotle, whom the Spanish monk Juan Gines de Sepulveda relied on for judging the rights of 'the Indians'. A 'natural slave', according to Sepulveda's interpretation of Aristotle, was a person whose inferiority and ignorance were such that only through servitude could the necessary human development be achieved. In Aristotle, this idea arose as part of a justification of slavery in Greek society; he sought to show that the slave's opportunity to work in the master's household was a chance to experience and learn the arts of civilization. Applying this to Spanish colonial rule, Sepulveda saw slavery as a necessary opportunity. The enslavement of the Indians of the newly conquered territories in South America, who lived far beyond Christian influence and teaching, was 'natural' – and it would bring them into the 'natural' joys and benedictions of the Christian Church. But slaves did not have the right to own property; those who did the enslaving had the right to take all the land and compel its former inhabitants to work for them.

Had it not been for King Philip of Spain, this quasi-Aristotelian justification for the dispossession of South American Indian peoples would have been long forgotten, a small footnote in colonial rationalizations of conquest and theft. In 1550, alerted by his legal experts to disagreements about the question of Indian rights to their lands, the Spanish king authorized a formal public inquiry – the first Royal Commission to deal with indigenous peoples. The inquiry took the form of a debate. On the one side was Sepulveda, very much the theorist: he had never set foot in the new colonies. He advanced the idea that these new peoples were 'natural slaves' and therefore had no rights that could restrict the claims of Spain's conquerors and settlers. The other side of the argument was entrusted to Bartolomé de Las Casas, a monk who had spent 30 years in South America and lived close to indigenous peoples there. He had been among agricultural, imperial societies – not the hunter-gatherers of Amazonia – and he had been surprised by complex and, in many ways, familiar kinds of social institutions. Las Casas had written extensively about his experiences, arguing that the Indians of the colonies had systems of law and administration, as well as ideas of property and morality, that should be respected. The debate lasted almost two years; the king of Spain then took 18 years to decide which argument he would accept. In 1568 he gave his support to Las Casas's point of view. Meanwhile, of course, Spanish policy and practice had been ruthless: Indians were deemed to have neither land rights nor souls. Some were enslaved, many were killed, and their lands were appropriated. Neither the sophistication of the Indians Las Casas described nor the vigour of the public debate in Seville moderated the conviction, shared by colonists and Christian missionaries alike, that these people had not yet reached the evolutionary level of real human beings.[2]

On the settlement frontiers of the North American colonies, the question of the Indians' humanity was also raised. If the indigenous occupants of the lands to which settlers were moving were not humans, but roamed, rather, 'as beasts of the field', then they had no right to resist the new Americans' 'manifest destiny' to take and use all new-found lands.

It is easy to see that an insistence on people's being something other than, or less than, human has been inseparable from the wish to occupy their lands. Doubts about an unquestionable right to appropriate land did effect some challenge to the theory of colonial expansion: legal justifications were sought to defend claims to new territories. At the frontiers themselves, however, colonists at times killed hunter-gatherers as if they were animals. Colonial governments licensed these murders by turning a blind eye, sometimes even condoning them as a suitable response to the 'primitives' and 'savages', whose want of humanity made them a threat to settlement. History records Aborigine hunts in Australia, the killings of Bushman families throughout southern Africa, attacks on the tribes of Amazonia, and relentless campaigns against the Indians of the American West. Early in the 19th century, the philosopher Hegel observed that the development of the American West had cost some 2 million Indian lives – an outcome he deemed to be a necessary part of progress.

5

The assertion that some humans are not human – or are not human enough to have rights – is absurd as well as brutal.

The Spanish *conquistadores* destroyed communities with elaborate agricultural and urban systems. They insisted that the Aztec were barbarous and undeserving of compassion, for they practised human sacrifice and cannibalism. In reality, the Spanish had arrived among people whose material wealth they wanted to plunder. The idea that the victims of this plunder were 'savages' was belied by the very thing the Spanish most wanted from them – the elaborate and magnificent creations of Meso-American artists, including worked silver and fine jewellery.[3]

In reality, explorers and adventurers arrived in the lands of societies that were at least equal to their own. Hunter-gatherers did not display abundant material goods or the technology of warfare, and they did not have the knowledge of mathematics, astronomy, engineering and textiles that was to be found in some indigenous societies of South America. But the Europeans who came ashore from those ships of exploration – dirty, malnourished and ill clad – encountered hunters and gatherers who showed all the signs of being well fed and healthy. The societies of these people were more stable and more secure than those of the explorers; they were also societies in which private and public well-being intertwined to ensure much fairer distribution of resources and greater social justice than the newcomers had ever experienced. But the representatives of 'civilization' did not hesitate to condemn as 'savages' the people who provided the food that kept them alive.

These encounters between unhealthy newcomers and vigorous tribal communities began in the 1400s and continued until the beginning of the 20th century. Another such paradox is to be seen in the history of European ideas. While describing the peoples they were discovering as inferior beings and claiming their lands for themselves, European travellers and intellectuals also began to extol the moral superiority of the peoples who were being conquered, enslaved and dispossessed.

Columbus's description of the very first Carib hunter-gatherers he met includes a recognition that they are 'so generous with all that they possess, that no one would believe it who has not seen it … and [they] display as much love as if they would give their hearts.' Social philosophers made intellectual use of what they saw as life that existed in pure nature. Hobbes's famous reference to life as 'nasty, brutish, and short' came from his imagining a society 'with no place for Industry … no Culture of the Earth … no Arts; no Letters; no Society.'[4] He wrote this in 1650, a critique not so much of the hunter-gatherer world as of the early capitalism of the England in which he lived. In subsequent centuries, philosophers as diverse as Vico, Montesquieu, Rousseau, Hegel, Engels and Marx[5] made use of the idea of a 'natural' human condition both to criticize the societies of their day and to celebrate 'innocence' and 'simplicity' – a core of deep human goodness – in peoples whom we would now call hunter-gatherers. In one context, these newly discovered tribes were savages whose conditions gave them no rights to life, liberty or property. In another, they became symbols for the human potential for goodness, equality and freedom.

These paradoxes point to the cynicism of the colonial project. The explorer Ralph Standish wrote in 1612 about the 'savages' he had met at the Cape of Good Hope.[6] Given their want of human achievements, it was, he said, 'a great pittie that such creatures as they bee should injoy so sweett a country.' The countries of the new worlds were indeed 'sweett' to the farmers who wanted to make them their own. Inca and Aztec silver provided wealth for the impecunious monarchy of 17th-century Spain; extensive grasslands and forest offered at least a hope of wealth to the landless settlers who had reached the expanding edges of European empires. In each place colonists claimed as their own, they concocted justifications for dispossessing people and taking their territories. To say that those they encountered were not human was the most general – and, in its way, the simplest – device for depriving hundreds of cultures and millions of human beings of their rights.

6

When Anaviapik and Ulajuk raised the question of how southerners have seen the Inuit, they expressed a concern that must have puzzled, alarmed and at times oppressed many, if not all, hunter-gatherers. They have experienced the attitudes of settlers and settler governments towards them. They have felt the consequences of the judgement that they, the original inhabitants, are not entitled to their own lands, languages and ways of life. They know that this judgement is somehow connected to a refusal by the colonists to see that hunter-gatherers have minds – a refusal that sits at the centre of the history of colonial misrepresentation.

The indigenous peoples of Canada have been forced to respond to a strong implication in modern legal theory that they do not qualify as fully human. This version of frontier racism has arisen in legal arguments about 'aboriginal title', the rights indigenous peoples may or may not have to their own systems, territories and resources. The legal and political actions that lie behind these contests over title are referred to in Canada as 'land claims'. For a century, various aboriginal peoples have had to make these claims. After his election in 1968, Prime Minister Pierre Elliott Trudeau maintained a long colonial tradition by insisting that the nation's Indians should be assimilated into the mainstream of national life. In 1971, Trudeau announced a change of policy from adamant rejection to circumspect acceptance of a land-claims process.[7] This shift resulted from a judgement in the Supreme Court of Canada in what is known as the Calder case – an action brought by the Nisga'a people, who argued that they had aboriginal title to their territories throughout the Nass Valley. Although the judges were split on the decision 3–3, the message was clear: aboriginal title did, after all, have some legal reality. Since then, arguments over who has which rights have been full of legal complexity. Land claims have at times appeared to define the nation.[8]

The term 'land claim' is itself an anomaly, implying that the onus should be on the original occupants to claim their homes, resources and territories from the colonists. This is a reversal of common sense; the burden of proof should lie with the newcomers. This reverse sense is a first indication of the onerous task indigenous groups have had to undertake. Their elders, historians and lawyers must find ways of satisfying criteria set by the Canadian courts for testing whether or not a claim can indeed be said to amount to a claim to aboriginal title. Litigants from hunter-gatherer and fishing societies have had to prove that:

- they use and occupy a definite territory to the exclusion of all other peoples;
- they have used and occupied the territory 'since time immemorial';
- they are 'an organized society'.

These tests have arisen from accumulated precedents in cases that reach back to the 19th century. But each of the particular requirements for evidence has been confirmed by Canadian courts in the 1970–1990 era. The problems inherent in proving the first two requirements – exclusive use and occupancy – are severe. In many hunter-gatherer systems, there are imprecisions and overlaps of territory that unsettle the demand for boundaries and boundary maintenance that the colonial model requires. For oral cultures to prove continuity of land use beyond the present generation, to the satisfaction of courts that rely above all on first-hand experience and written documents, is also a daunting undertaking. The imposition of legal process and rules on the peoples the colonists have sought to dispossess makes it hard for hunter-gatherers to give evidence of their own kind in their own way. But the difficulties that arise with questions about use and occupation of land do not challenge the hunter-gatherers' humanity. It is in the 'organized society' test that the deepest prejudices reveal themselves.[9]

What are the qualities by which society is judged to be organized? Rules and conventions of behaviour, shared economic practices, common religious beliefs and customs – these things *are* society. To speak of society is to imply organization. People who live without a shared set of values and rules cannot live as a people. The human condition is composed of social realities. And the central indication of this is language.

Language and society are inseparable. Each is a necessary condition for the other. Children who grow up without any form of society do not learn to speak; human societies do not exist without language. The organization of the human mind requires a community of fellows who speak to one another, sharing and thereby teaching the words and rules that constitute the language. We know what words mean because they are used by a group of people to mean things. Society has an existence because it is composed of people who share these meanings and who use them to share everything else that makes human life possible.

To suggest that there are human beings who might live without 'organized society', therefore, is to say that there are human beings who live without society at all. To suggest that a people might live without society is to imply that they are living without language. And to imagine a people without language is to suggest humans who are not quite human.

Think of an elder on the witness stand being quizzed about whether her society is 'organized'. Are there laws? the lawyers ask. Do you have rules about your ways of using land? Do you collaborate? Do you live in anything that we can call a society? To experience this kind of interrogation is to endure scepticism about the obvious. The suggestion is that your people have not lived long on their lands, that they have not lived there in the belief these lands are indeed theirs and no one else's, that they are not attached to these lands in any profound way, and that they do not have customs or beliefs uniquely their own. To answer these kinds of questions is thus to respond to insults. Aboriginal people who take the witness stand in land-claims cases often have an intense feeling of not existing; their history, their homes, the integrity of their grandparents are all contested. To be obliged to prove that which defines you is to have a sense that your very humanity is in question.

7

Imagine the crowded, roaring bar of the George on 96th Street, Edmonton, a Prairie city in the Canadian midwest. The George is a rundown beer parlour in a part of town where no one goes. No one, that is, except drifters, down-and-outs and hard drinkers. There are Indians, some hookers, winos from many backgrounds. It is a place to have friends who don't ask questions, providing warmth that has nothing to do with family or home and a chance to lose any sense of weakness. The tables are crowded; the noise is a shrill mixture of shrieking laughter and shouted conversation; fights break out. A tough place. But for all its toughness, the men and women who come here are far more often generous to one another than they are belligerent. Everyone has almost nothing; people give out drinks, cigarettes, small change and advice about where to bum a hot meal. Everyone belongs because they have all chosen, for a while at least – maybe a week or maybe a year – to belong nowhere.

I went to the George every day for a few months in the spring and summer of 1969. It was my first fieldwork in Canada and my first encounter, therefore, with 'Indians'. In this and other bars, on street corners, in abandoned shacks and at the edges of a park, I talked and drank and laughed with men and women whose lives reached into the Plains of the Midwest, to the Pacific Coast and to the forests of the Subarctic. They spoke to me of spending time 'in the bush', away from 'the white man'. Sometimes, at night, when a slight drunkenness had not yet given way to incoherence, when sadness rather than defiance or humour was the mood of the moment, a few of those I knew best would tell me they would soon be heading home. But I was never sure what home meant or just how many of them would be able to get there.

One of the first people I met in Edmonton was Harry. A tall, heavily built man of about 50, with the strong features of a Plains Indian, he was leaning on the wall outside the George, playing a harmonica. The music was beautiful – a bubbling of sounds, fast and rich, with a blend of tunes that I learned later was part Scottish and part Cree. It was the music of the fur trade, of the encounter between those who manned the trading posts and bought the furs and those who trapped and sold them. I stopped to listen. Harry watched me as he played, then paused and asked if I had a quarter to spare. 'Sure,' I said. I handed him 50 cents. He looked at the two coins, as if measuring their possibilities. 'Good,' he said. 'Now you and me can go buy a few beers.'

Harry became my best friend on skid row. He was a good friend to have. Everyone knew him, and many took pride in his musical skill. He played the fiddle as well as the harmonica, and knew where he could go to find both cups of tea and instruments that he could borrow. He made money by busking on street corners, but only enough to fund more rounds of beer and the occasional bottle of cheap sherry. I suppose he was an alcoholic, but he never got rotten drunk, and he somehow placed himself at a distance from those who did. He was courteous and helpful, and a bit of a street-person social worker: he would take care of those who were most destitute, and he did what he could to prevent fights from drawing real blood.

One Sunday, when the bars were closed and the skid row community broke into little clusters of people on street corners and vacant lots, Harry told me to come and hear some real music. He took me to a bootlegger who sold us a bottle of the cheapest sherry, then led me to an abandoned house a few blocks from the George. It appeared to be boarded up. But Harry knew a way in through a broken door to its basement. Down there, in the gloom, a group of men and women sat in a circle. A few bottles stood around, and one man was unconscious in a corner.

We joined the group. No one said much, and then two or three people began to sing. Then another few people; a different song. It was Algonquian music, with drumbeat rhythms tapped out on a broken chair and the floor, the voices high-pitched, the words a strange and haunting wail. The singers sat with their bodies hunched a little forward and their eyes shut tight. They strained to get the sounds right, to keep the rhythm, to take and keep themselves elsewhere. This was no longer skid row – or was it actually the very heart of skid row, where those who lived as marginals could be themselves at the centre of the white man's city?

The songs were separated by quiet pauses, a hand passing the bottle, a shifting of bodies, but no one spoke.

After one of the songs, a young woman broke the silence and said to me: 'Now you hear our minds, in our song. How come the white man says we have no mind? When they hear a Cree song, I guess they think it's a coyote howling.'

Everyone laughed.

8

20th-century cameras have allowed us to look into the eyes of the wildest of animals. There is no corner of nature, however remote or small or dangerous, that does not appear in intimate proximity on television screens. At the same time, researchers into animal behaviour and its genetic sources are developing ever more sophisticated techniques for seeing the mechanisms and achievements of the natural world. There is a new kind of relationship, based on technical sophistication and the knowledge of experts, between humans and the rest of nature. Photographers and scientists are the wizards, if not the shamans, of our age, making revelatory journeys into places where, in the course of ordinary life, the rest of us cannot go. We rely on them to show us the world that is not human.

This ever-increasing closeness to the natural world influences our sense of the dividing line between human and animal. We discover an unexpected complexity of animal systems and learn about the intricate links between one animal and another. We find that there are divisions of labour, with one part of an animal community raising newborns, others getting food, and others defending the group. We are shown the sophisticated behaviour required to capture or evade capture, elaborate forms of courtship, and myriad forms of communication. We discover that leaf-cutter ants make gardens and harvest crops; that gannets can recognize their own nests among a hundred thousand others; that humpback whales coordinate their fishing; that in some species, monkeys can warn one another about several different kinds of impending danger; that male fruit flies sing elaborate love songs to court females. These are occupations and purposes that we understand. They depend upon qualities, characteristics and motivations that humans also possess. Detailed portraits of the natural world again and again reveal similarities between humans and other beings. The evidence of DNA, with its apparent overlap of gene sequences between mushrooms and people, is the newest way in which the lines between us and the rest of nature can seem to be uncertain.

This apparent blurring of the divide could also be seen as an echo of shamanism. Perhaps the boundaries around the human are less definite, more porous, than most scientists and many farmers have tended to suppose. Animal rights advocates often make this kind of argument; they point out that the use of animals for experiments, or even as food, depends on human beings keeping animals in a separate and inferior moral category. The promise of Genesis is integral to the domestication of animals and to their use as a resource. The exiles from Eden go forth and have dominion.[10]

In fact, real shamans – as opposed to those who provide wildlife programmes for television or make new-age forms of argument – say that humans and animals exist in separate domains. In the shamanic myths of very ancient times, humans and animals lived in the same circumstances, able to speak and procreate with one another. But these myths also tell of how ancient times yielded to an era in which the divide between humans and other creatures became much clearer. Indeed, the need for shamans, or for spirit possession, derives from the periodic need to cross this divide. Hunter-gatherers and their shamans insist that life depends on maintaining the right kind of relationship with the natural world, and the negotiations necessary to sustain this relationship are difficult. The power of the shaman centres on this difficulty. By overcoming it, the journey can be made from human to animal and back again. This is the power that comes from transformation.

When we look into the eyes of animals, be they pets or creatures that we hunt, cows and horses on the farm, dogs in our homes, or the subjects of wildlife documentaries, we seem to see thought. Animals watch, wait, appear to ponder. They look as if they are assessing one another's movements in order to make sure that their own are safe or effective. They give many signs that they are thinking.

In 1999, British television broadcast a wildlife programme made with a new level of film technology: it had become possible to film in almost complete darkness. The footage included sequences of lions stalking and killing their prey. They moved with great stealth, peering, watching, calculating, manoeuvring. Several individuals collaborated to approach and surround their prey; two remained still, one continued to move closer. Then, with great skill and precision, they made their attack. Were they thinking? Surely they must have been. To calculate in this way, to make decisions about how best to carry out the kill, must require some form of thought. Or is this so? It is very hard to imagine thought without language. And these lions do not speak; they have no more than the most minimal form of vocal communication. Their brains work without words.

This wordlessness is integral to how we see animals. It arouses in us a form of gentle sympathy, an anthropomorphic kind of pity. It also means that, for all their ferocious killing of weaker species, we see animals as innocent. Those lions do not lie, because to tell a lie requires speech; they cannot be condemned for the cruelty of their ways, because morality arises only with articulate thought, in words. The lions show a kind of purity of judgement, rather like pure emotion. There can be no process of the kind that depends on thinking as a silent form of speech. Lions do not talk to themselves. When we look at them we see, rather, the strange dumbness of the animal as it thinks without thoughts. We see feelings that we recognize, of course: fear, excitement, even pride. These feelings also arouse our sympathies. But animals are untainted by the ambiguities and distractions and complexities of what humans know to be the heartland or even defining features of thought.

9

'What, then, is the difference between brute and man? What is it that man can do, and of which we find no signs, no rudiments, in the whole brute world? I answer without hesitation: the one great barrier between the brute and man is language.' These are the words of Max Müller, among the first theorists of language, writing in 1875. Müller's view has been shared by many others, including late 20th-century scientists who have sought to identify the part of the brain where the potential for language resides. Language theorist Derek Bickerton observes that language is probably 'the antecedent of most or even all of the other characteristics that differentiate us even from our closest relatives among the apes'. The miracle of this ability to understand, use and make language is the miracle of being human. 'Simply by making noises with our mouths, we can reliably cause precise new combinations of ideas to arise in each other's minds.'[11]

There has always been a popular view, endorsed to some extent by Darwin's ideas about language, that places the calls of birds and the cries of animals on a single spectrum of communication. This is to say that humans do the same as animals, except that they do it more and better. Yet the attempts of primatologists who spend years teaching a chimpanzee to recognize and in some way make use of four or five words, or the intensive efforts of marine biologists to decipher the communication systems of dolphins, are projects that seem to confound any claim that even the most intelligent of other mammals have anything like language. They communicate, but they do not have language. There is no equivalent of grammar or syntax; no parallel, therefore, to the way human children learn to speak. Animals do not do what humans call thinking. They may exist in a Zen-like state, where the brain works without self-consciousness (consciousness is also inseparable from words), but they are not thinking. This is why animals are outside moral judgements and why, also, they inspire such a sense of puzzlement. To look into their eyes is to see a creature with a brain. We see facial expressions and even gestures that are very like our own. Yet something is missing.

We humans may be able to get a sense of animal 'thinking' from our remarkable capacity to make quite complex decisions without thought. The driver of a car who suddenly has to deal with an emergency is capable of making a quick set of decisions – changing gears and speed and direction – without any apparent thinking. Similarly, drivers of cars often have the experience of picking the route home without being aware of doing so. Actions of this and many other kinds are said to be unconscious, in that the thinking takes place somewhere other than where we are using – or are aware of using – language. The terms 'mindless' and 'thoughtless' indicate the significance of action that fails to proceed from the necessary mental processes: such behaviour is wrong, in either a moral or a practical sense, precisely because we did not think – that is, we acted without the benefit of words.

In mythology and literature, creatures that are almost human are often monsters. Their animal characteristics are exaggerated in a symbolic manner: they represent the frightening power of the animal in ourselves. These creatures are somehow primitive or savage; they take human shape, yet are outside human culture. And their condition draws its most poignant qualities from their lack of articulate language. Prospero's Caliban, Beauty's Beast, King Kong, Marian Engel's Bear. The stories in which such characters have greatest effect are those in which they are discovered to be innocent despite their apparent beastliness. They are without the guile of language.

When human beings began to use language, their brain structure made an evolutionary leap of huge importance. The physiological difference between those who spoke and those who did not may have been very small, a tiny fraction of the total brain. But once it was there, a divide opened up between human beings and all other animals, a divide that had immense and ever-expanding consequences. Language allowed human evolution to take a very different and much more elaborate path.

In the absence of language, inheritance is limited to the gene pool. Parents pass on to their offspring a bundle of genes and very little else. But with language, they can pass on vast bodies of knowledge, moral codes, forms of social arrangement. And with language, it is possible to think. With thought, it is possible for each generation to transform knowledge and ideas, which are then passed on to the generation that follows. Once it had language, the human species spread throughout the world, from environment to environment, each group with its own ways of occupying territory, knowing about their land and ordering their lives in a particular region. In this way humans came to live in cultures – that is, in many kinds of articulate and organized societies.[12]

The human mind is this combination of language, thought and culture. The capacity to be human is inseparable from the capacity to think, be articulate and change life through words. The best-trained chimpanzee and the least-educated human being are far, far apart in linguistic skills. The one has nothing more than a tiny number of words it can use in restricted conditions. The other has grammar, syntax and hundreds of words that he or she can use in any circumstances. The human mind, at its least, is rich with potential that makes human evolution unlike anything else in history. All the mind's capacities are shared by all humans, irrespective of any other consideration. Each culture may give rise to its own kind of mind. But mind is what gives rise to culture itself.

10

No one knows when human beings first used language. *Homo erectus*, the human ancestor who lived about 2 million years ago, used tools and has been declared by some archaeologists to have had many qualities that are more human than animal. But the kind of tools *erectus* used seem to have remained unchanged for about a million years, and the structure of its upper body suggests that it did not have the breathing system necessary for elaborate speech. As one scholar has put it: 'If these ancient people were talking to each other, they were saying the same thing over and over again.'[13] The evidence that does suggest language, where the tool kit is complex and changing and where the physiology of the upper body is consistent with the use of speech, comes from about 800,000 years ago.

The dating of the acquisition of language, however, is less important in this context than the nature of the process. Did language appear through a long and gradual evolution, with lower levels of linguistic achievement giving way to higher levels? Or was the ability to use language a more sudden, cataclysmic event, or set of events, which meant that humanoids became humans in a revolutionary change to the mind? The importance of this issue is very great. A slow process means that different peoples could have been at different levels of linguistic ability, or that languages with different forms of linguistic sophistication could have emerged and disappeared. A revolution means that a single evolutionary development created the mind of the original *Homo sapiens*, the ancestor of all modern human beings.

Various kinds of evidence suggest an answer to this question. There is, first of all, what seems to have been a sudden explosion of human culture – the great spread of hunter-gatherer systems around the world, each with its own sophisticated and specialized technology. Then there is the evidence of language itself. What has been called 'the language instinct' turns out to be fundamental to the activity of all human minds, even those denied the normal means to develop language. Every child acquires or uses grammar, irrespective of the circumstances. And given even minimal language-learning opportunities, children begin to employ grammatical techniques with astonishing speed, soon applying linguistic rules and making their own sentences – ones that they could never have heard before. These findings suggest that the capacity for language developed in a short period of time and by means of a specific evolutionary leap – the ability to acquire and employ grammar.

Some experts have argued that the ability to learn a language is 'hard-wired' into the human brain.[14] By this they posit the existence of a faculty that serves as the language-learning element in the human mind. In other words, this is the capacity to be a human that all humans inherit; and it is this capacity each society then relies upon to build its particular array of knowledge, skills and norms. The immense evolutionary advantage that came with this hard-wired faculty lay in the way humans could think, know and distribute resources in collaboration with one another, in ever-changing ways. The social dimension of language is thus intrinsic to both its form and its opportunities.

These pieces in the jigsaw of human prehistory can be assembled to show a picture of human beings living in groups that use language, and therefore thought, to deal with all their concerns. The universal qualities of mind mean that humans are able to learn one another's languages. One person knows more or less than another. One person is more eloquent than the next. But all of us share the faculty that makes eloquence possible.

Languages rely, of course, on the sounds that people make. Linguists have identified some 140 separate pieces of sound – the total for all the world's ways of speaking. English uses about 40 of them; Norwegian, the most elaborate vocal system of all Indo-European languages, uses about 60; Inuktitut uses about 50; there are Bushman languages in southern Africa that use about 120. As one of the world's most eminent linguists has said, the Bushman is 'the acrobat of the mouth'.[15] This wide range of sounds does not suggest that the sophistication of a particular culture has any links with the outward complexity of its language or languages. Nor are there differences in grammar that indicate any one language is more or less evolved than another. The popular idea that some languages are 'primitive' is false. Each language has its own sophistication, but all share a basic level of intellectual achievement.

The Khoisan languages, which may have the most direct links to the birthplace of language itself, have been despised by Europeans as 'the chattering of monkeys'. In reality, the Khoisan use about 85 per cent of all language sounds. This is not to argue that their languages are *more* complex or can therefore achieve greater intellectual heights than those of other peoples. The point is that they are not *less* complex. There is no relative simplicity of language. The underlying faculty for language, the hard-wired component of the human brain, is universal: an ultimate equality of opportunity.

11

The brain struggles when it comes to thinking about thinking. Being able to speak, however, may have much in common with other kinds of human natural potential – to have arms, for example, or a particular arrangement of nerves. Noam Chomsky, the most influential modern theorist of language, has described an important implication of the similarity between the capacity for speech and other capacities:

> No one would take seriously the proposal that the human organism learns through experience to have arms rather than wings, or that the basic structure of particular organs results from accidental experience. Rather it is taken for granted that the physical structure of the organism is genetically determined.[16]

Chomsky makes this self-evident observation to support his proposal that the underlying feature of language – the thing in every human brain that makes language possible – is also a physical structure that is genetically determined. Chomsky situates the source of language, the piece or pieces of the brain that make language possible, alongside other faculties that are inherited rather than learned. In the same context, he goes on to ask: 'Why, then, should we not study the acquisition of a cognitive structure such as language more or less as we study some complex bodily organ?'

According to Chomsky and other researchers, the speed at which a child's vocabulary grows, and a child's ability to use grammatical rules, are not influenced by teaching. Studies have found that attempts to correct children's grammatical errors by repeating the correct form back to them are unsuccessful. Researchers looking at cases where parents corrected their children's English found that this correcting 'had no effect – if anything, it had an adverse effect – on the child's subsequent development'. This research, and the discovery that children do not respond to being taught correct grammar, is discussed in Steven

Pinker's remarkable book *Words and Rules*, which builds on many of Chomsky's original insights.[17]

Pinker focuses attention on irregular verbs as indicators of how the brain acquires, builds and uses grammar. In this context, he looks at studies of identical twins, noting that 'vocabulary growth, the first word combinations, and the rate of making past-tense errors are all in tighter lockstep in identical twins than in fraternal twins'. Pinker's striking conclusion to a chapter centred on the relation between nature and nurture in language learning is clear enough: 'Every bit of content is learned, but the system doing the learning works by a logic innately specified.' This account of language learning establishes that every child inherits a fundamental set of characteristics prior to and independent of culture. These create the possibility of language and also set the limits to what can be taught.

Findings from the modern heartland of linguistic theory are consistent with hunter-gatherer ideas of child raising and education, in which children are expected to develop in their own ways, at their own pace. Nature is relied upon to do its part in the business; the mind is expected to grow very much on its own. Pedagogy is viewed as of limited benefit at best, and as counterproductive at worst. Children learn when and what they are ready to learn.

In Inuktitut, there is a linguistic indication of this faith in the extent to which human potential is hard-wired. When a person experiences extreme grief, he might say '*Isumaga asiujuq*'. 'My *isuma* is lost; I am out of my mind.' When Anaviapik's son Inukuluk was talking about his experience of adult education and his struggle to 'be a white man', he began what he said with '*Isumanguar*', 'appearing or pretending to think', which I translated as 'I sort of thought'. And in many conversations I heard '*Isumatuinnarpunga*', 'I just thought', a caveat that conveys the sense of the English words 'It's only my opinion'. The root *isuma* has many uses; they show it to be something that also has an independent existence. In Inuktitut, thought is tightly linked to the capacity for thought.

When a child misbehaves or misunderstands, adults are likely to say '*Isumaqijuq*', meaning that she lacks *isuma*, is without the necessary thought. It is striking that in this use of *isuma*, the child is no more blamed for this lack of thought, for having an undeveloped *isuma*, than she could be criticized for having short legs or a large nose. Everyone is aware of a child's development, in body as well as mind. Comments are made noting progress. These comments are not judgemental, though they will, of course, have their effect. Social pressure comes from what a child hears said about her. Adults do influence the way a child learns, shaping aspects of character and affecting the rate at which many kinds of learning take place. But the Inuit trust that individual development comes from what goes on in the child, not from any systematic pedagogy. *Isuma* grows at its own pace. A child has the potential, and she will grow in her own good time. Once the capacity has developed, and there is a mind and language that expresses mind, then some children will learn better than others. External factors come into play, just as they do with the strength of arms and legs. But for hunter-gatherers, the individual mind is the thing that must choose to learn, develop, make decisions. Pressures from others on that mind, according to the deep beliefs and social conventions of hunting peoples, are more destructive than instructive. The mind has the capacity to learn, and, left to develop on its own, it will do so.

The place of thinking in Inuit ideas of psychological development, and the related ways in which the word *isuma* is used, offer many clues about Inuit society. Parents identify children with respected elders, trust children to know what they need, do not seek to manipulate who children are or what children say they want. This way of treating children tends to secure confidence and mental health. And Inuit child raising is inseparable from many aspects of interpersonal behaviour. Adults respect one another as separate but equal. This is the basis for cooperation – by respecting individual skills, judgements and knowledge, the strengths of the economy and the social order are shared. *Isuma* is the notion that underlies and unites many of these features of Inuit life, for it affirms that in crucial ways the development of *isuma* is independent of social manipulation and control. Embedded in this use of the word for mind is a view of mind itself.

The work of Chomsky and Pinker and the Inuit use of *isuma* reveal the same truth: there is some logical and physiological antecedent to the cultural specifics of learning. In the hunter-gatherer reliance on individual egalitarianism lies the freedom for everyone to be themselves, and a confidence that the integrity of society – the respect that hunter-gatherers show to one another as well as to the natural world around them – will achieve the best results for both individuals and the group. The egalitarian individualism of hunter-gatherers is of a piece with a compelling theory of mind.

12

The linguistic theories of Noam Chomsky have been closely associated with the school of thought, or the theory of thought itself, known as structuralism. Structuralist theory originates with ideas about grammar and its relation to the structure of the mind, and it relies on the view that grammar has at its heart a logical principle akin to the law of excluded middle, the principle that nothing can be both X and not X at the same time. The merits of this approach to grammar may well be inseparable from the insights of Chomsky and others into universal grammar. But anthropology made structuralism its own with a series of assertions about a seemingly fundamental dichotomy between culture and nature. Beginning with these ideas as a way of looking at ritual and myth – seeing rituals and myths as expressing or mediating the need for humans to establish their cultures in defiance of nature – structuralist anthropology then proceeded to explore many other kinds of dichotomies, some of which resonated with the culture : nature paradigm. Man : woman. Dark : light. Raw : cooked. Upstream : downstream. Sky : earth. Sun : moon. Human : animal.

The anthropologist who made the most elaborate play with pairs of opposites, and who originated the claim to see in them a clue to the nature of the human mind itself, was Claude Lévi-Strauss. Lévi-Strauss's followers in the English-speaking world were led by Edmund Leach, who for many years was professor of anthropology at the University of Cambridge. Their views became an orthodoxy. No ritual or myth, no piece of social life or sacred text was safe from a grid of interpretive dichotomies. This 'structure' was set out as if it were an explanatory reduction of social and intellectual life, a scheme that laid bare some primary meaning.

When I first read Lévi-Strauss in 1967, I was impressed by the originality and apparent insight of his way of writing about both tribal and European cultures.[18] In *Tristes Tropiques* and *The Savage Mind*, and then in his ever-burgeoning *Structural Anthropology*, Lévi-Strauss carried a generation of intellectuals on a wave of ideas that began with Cartesian philosophy and proceeded to overtake all branches of sociology and philosophy. This was work that addressed central questions about reason and mind, while taking the reader to tribe after tribe. Lévi-Strauss's description of the Nambikwara, hunter-gatherers of the Amazon, was both compelling and poignant. Here were people whose material simplicity was matched by extraordinary cultural beauty, and yet they were disappearing from the world. His account of the myth of Asdiwal, collated from Nisga'a stories set in the Nass Valley, with its hero figure moving up and down the river and between the earth and the sky, was analysed into binary pairs as if it were underlain by a kind of mathematics of human consciousness.[19] To read this work was to experience a sense of intellectual wonder, to feel that one was being led on a journey of remarkable discovery. Yet the journey was oddly frustrating, as if it passed through fabulous landscapes but never reached a destination. The ideas floated high above reality, circling; and many of us circled up there with them, not sure where we were or where we were going, in awe of the height, feeling uneasy, but not quite daring to land. Over the years, the magic of the journey faded; a sense of dissatisfaction remained.

In retrospect, the trouble with the intellectual claims of structuralism is not hard to discern. To say that a tribal myth contains opposing elements, and that its structure is demonstrated by laying these out in a formal manner, revealing at the same time dichotomies that are otherwise obscure, is to explain nothing. The analysis may well claim that a reduction of these pairs shows them all to be expressions of the fundamental opposition of culture to nature. But what is the explanation being made of the myth? The myth expresses the core issue of all societies: to establish how human life seeks to separate itself from natural life. Or the myth expresses the deep nature of human mind, the structure of mind itself, where dichotomies lie at the heart of us all. But these are not explanations of anything. To say that a myth expresses the core of society and the nature of mind is to say very little. Myths and ritual are the products of language and society; it would be strange indeed if they did not give expression to them.

Structuralism in anthropology is an elaborate and at times fascinating game. It looks scientific, for it has a direct link with scientific linguistic theory and follows scientific methods of exposition, deducing an underlying reality from social, verbal and textual surfaces. But there is no explanatory achievement that goes beyond an a priori assertion about the structure of mind and a somewhat tautological process of deduction: the theory knows what it is going to find, then relies on a thorough but predictable exposition to find it. It is very striking that when Edmund Leach wrote about the Bible, and gave himself the task of explaining the nature of much of the text, he showed how a particular complexity of the stories is in the interest of a priestly class. Here is an explanation, but it is to do with function, not structure.

A further objection to structuralism in anthropology is more down-to-earth. The use of binary pairs to create an analytical grid is at odds with the way in which indigenous cultures, starting with hunter-gatherers, achieve so much by avoiding dichotomies. Hunter-gatherers also reject any complete reliance on deductive reasoning. So the structuralist analysis that commits from its outset to display the inner workings of dichotomies is in a perplexing, and somewhat imperial, relationship to its subject matter. The anthropologist's ways of thinking here occupy the intellectual territory, obscuring and ousting the people's own modes of thought and discourse. An irony of Lévi-Strauss's achievement is that it yields much more insight into his own culture, so centred on binary logic and attempts to create rational order, than into those of the tribes he examined.

Postmodern work in literature and social science has emerged in part from frustration with this structuralist reliance on dichotomies and its attendant pseudo-scientific qualities.[20] These new approaches to history, culture and knowledge centre on meaning rather than on mind. And they pay close attention to the ways in which meanings themselves are constructed by the would-be analysers. Thus postmodernists deconstruct the accounts, be they myths or theories of myths, allowing presuppositions, intentions and colonial purposes to disclose themselves in whatever array of complexity or contradiction may emerge. It is easy to imagine the intertwining puzzle that this exercise in scrutiny can yield.

The postmodern task is the analysis of analyses – an approach that can indeed yield insightful theories about theory. Its problems, like those of structuralism, stem from a failure to describe a world whose reality would be recognized by those who spend their days living in it. The deconstruction of hunter-gatherers has contributed to the view that they do not exist at all; they become, instead, a myth of colonial theory, a part of someone else's ideology, or, at best, an edge of some other way of life. To those who live, or whose ancestors have lived, by hunting and gathering, this deconstruction must come as a surprise.

13

Let me return for a moment to dichotomies, this time to the pair of terms that I have relied upon not only for the writing of this book but in much of my thinking about the world. In my notes and letters, places where writing is not laundered for fear of critics, I have long used the pair of abbreviations h-g : p-g. These stand for hunter-gatherers and potato growers. This pairing began as a small and rather obscure joke about the romantic appeal of hunter-gatherers in their vast territories opposed to the confined, harsh lives of peasants in their fields of potatoes. The joke – if it can claim to be more than a piece of grim and private humour – needs some explanation.

I began anthropological work in the west of Ireland. I spent long periods of time living and working with men and women whose lives centred on small gardens and a few fields. This was an experience of peasant life. And all the notions and tensions of what it means to be a farmer in Ireland turned my attention to potatoes. The history of the families I knew, and the stories of their farms, had been shaped by the potato. Peoples' attachment to their fields, their occupation of the hillsides and bogs and islets of the west coast, were made possible by potatoes. They could live on ever smaller areas of ground and still feed large numbers of children thanks to the potato's remarkable productivity and nutritional value. The shattering of this system, the breaking of the cycle whereby each family would divide its holdings to allow the sons to inherit land, and in which sons and daughters would marry young and begin their own households, was the result of the potato famine of 1846–1851.

The Ireland I knew had its roots in the changes after the famine.[21] Not that the potato was gone; rather, it could no longer be the basis for an ever-increasing farming population. Modern Ireland was born of potato blight and a population that was declining fast. The language of modern Irish writing (some of James Joyce, Samuel Beckett, Sean O'Casey, Patrick Kavanagh, even Seamus Heaney) reflects all this, though I know there is a harking back to the 'real' Irishness of pre-famine days in Yeats and Synge. These Irish 'traditions' were of short duration, but the potato was always there. It shaped the harshness of the work and became the condition of both attachment to the farm and the inevitable emigration of so many to other places. The history of the potato in Ireland provided a chance to see, in stark and clear form, the reasons for and consequences of the exile from Eden. Here were peoples who were indeed enduring the curses of the God of biblical creation. They lived by the sweat of their brows, gave birth to many children, then had to go forth and multiply elsewhere.

After living in and writing about Ireland, I travelled to the lands, lives and stories of hunter-gatherers. I have already described the intense feelings this gave me of making a journey to a very different kind of human condition. The immense landscapes were matched by human beings who seemed to be free and at home. I had made a move from the realm of troubled exiles to the other side of Eden. Through this move I was to discover a contrast that was both personal and anthropological: I felt liberated from the anxious inner landscapes of middle-class Europe, and I was able to experience the warmth and ease of people who have the deepest possible sense of being in the best of all possible places. So the h-g's came to oppose the p-g's, the hunter-gatherers the potato-growers.

One absurdity of this construct is obvious enough. Potatoes came from the Americas, and were domesticated there, I would imagine, by peoples more in the hunter-gatherer mould than in any other. There must be a better agricultural abbreviation, one that refers to some resource other than potatoes. The obvious candidate is g-g, grain-growers. At least this makes a childlike pun on the existence of the horse (gee-gee), though this is a creature that can leap across the divide – as, of course, it did when Indians in the Plains and the North-west got hold of horses in the 1600s. In fact, the h-g : p-g abbreviation, along with its alternatives, should be put aside so that other weaknesses of this dichotomy may be confessed.

Hunter-gatherers rely on wild animals and plants. But there are many indigenous societies that depend on domesticated animals and crops – tribal peoples who are not hunter-gatherers. Relations between these two forms of indigenous economy are often marked by mutual suspicion and animosity, with tribal agriculturalists tending to despise their hunter-gatherer neighbours. James Woodburn, the British academic who has made some of the most important contributions to hunter-gather anthropology, summarized the kind of discrimination that hunter-gatherers have suffered from their pastoralist neighbours in southern Africa, noting that they tend to be described as 'dirty, disgusting, gluttonous, ignorant, stupid, primitive, backward, incestuous, lacking a proper culture and language and even as animal-like, not fully human.'[22] He goes on to explain how these attitudes are often accompanied by deep fears about the apparent exotic powers of hunter-gatherers. The important point here, however, is that the divide between agriculturalists/pastoralists on the one hand and hunter-gatherers on the other appears between indigenous societies as well as between hunter-gatherers and European settlers. Both the sociology and the colonial histories of Australia, North America and southern Africa justify, and can be illuminated by, some version of the h-g : p-g distinction.

In the Americas, some indigenous agriculturalists developed the dense populations, severe inequalities and military aggression that I have linked to settler farming. Similarly, to reflect on the ancient history of Europe, where farmers occupied hunters' lands millennia ago, is to contemplate the possibility of many mixed economic systems. Farming peoples moving into new lands would have relied on herds and hunting while they established fields and waited for crops to grow. Some hunter-gatherer societies, having exhausted their supplies of wild game, either adopted a form of agriculture or pastoralism or entered into complex dependence on neighbours who were farmers or herders. And hunters in many regions may well have tried to farm or make use of domestic animals as adjuncts to their hunting systems. The evidence of language, as I have said, argues that the farmers overwhelmed the hunters. But this does not mean that farmers were not also hunters or that the hunters, before being overwhelmed, did not attempt some farming.

Anthropological accuracy requires, therefore, a great deal of caution about the hunter : farmer dichotomy. In reality, there is a possible spectrum of economic systems – with hunters at one end, farmers at the other, and many kinds of mixture in between – rather than two exclusive categories, some pairs of opposites that between them include all possible human societies. In this respect, the hunter-gatherer : farmer divide is itself a form of myth.

Nonetheless, I believe that within this distinction lies a set of intellectual and imaginative opportunities. Thinking about the place of hunting peoples in the human story offers an insight into the history of the world. It provides a parallel insight into the nature of the human mind. The destiny of the hunter-gatherer is both an external and an internal process, an issue for societies and for individuals.

14

The hunter-gatherer mind is humanity's most sophisticated combination of detailed knowledge and intuition. It is where direct experience and metaphor unite in a joint concern to know and use the truth. The agricultural mind is a result of specialized, intense development of specific systems of intellectual order, with many kinds of analytical category and exacting uses of deductive reasoning. The hunter-gatherer seeks a relationship with all parts of the world that will be in both personal and material balance. The spirits are the evidence and the metaphors for this relationship. If they are treated well, and are known in the right way, and are therefore at peace with human beings, then people will find the things they need. The farmer has the task of controlling and shaping the world, making it yield the produce upon which agricultural life depends. If this is done well, then crops will grow. Discovery by discovery, change by change, field by field, control is increased and produce is more secure. The dichotomies of good and evil, right and wrong express this farming project: control comes with separating manipulable resources from the rest of the environment and working with determination and consistency against all that might undermine this endeavour.

The differences between hunter-gatherers living before agriculture developed or beyond the later farming frontier, and small indigenous societies based on a mix of farming, herding, hunting and gathering, may not best be understood as issues of mind. As noted, ideas about spirituality and the boundaries between the physical and the metaphysical are shared by many indigenous societies, both hunter-gatherers and small-scale farmers. However, all agriculture depends on controlling and remaking the natural world, and farmers have the task of both defending their fields and finding new ones. These are social and economic reasons for relatively high levels of organization and aggression. It is no coincidence that in so many parts of the world, including regions where different indigenous systems live alongside one another, agriculturalists despise hunter-gatherers for being 'primitive' and hunter-gatherers complain that farmers are belligerent. In the colonial era of the past 500 years, 'developed' agricultural societies have launched themselves with particular ferocity against all other peoples, and have, in particular, sought new land in vast territories occupied by hunter-gatherers. However complex the overlap between different kinds of indigenous societies, the dichotomy of hunter-gatherer : farmer says a great deal about how the world and the mind have been shaped.

Two ways of being in the world yield two kinds of human condition, each with its own set of circumstances. History reveals that exponents of the one have made war on the other, and the world has changed accordingly. Yet these different ways of thought are, as potential, within everyone. Human beings can reach into themselves and find two versions of life, two ways of speaking and knowing. Internally, many people are torn between these two ways. Individuals are born into one or the other society, and therefore learn its particular skills and disposition; but nobody is born to be either. The potential for language, and therefore for thought itself, is a shared human characteristic. The specifics of the language that are learned – not language itself – are what embody the intellectual and personal characteristics of one or another kind of mind and society.

What makes us who we are? Things we inherit, be they aspects of body or the hard-wiring of the mind. But language means that much of who we are does not lie *within* us as individuals so much as *between* us. The child is shaped by the society she lives in as a result of how others speak and behave towards her. All of us learn and live in relationships with one another: much of our reality lies in how these relationships take shape, function and maybe fail. Much of who people are comes from events and processes that are more than just internal and personal. And this is where we can see a particular importance of hunter-gatherer societies: they have established and relied upon respect for children, other adults and the resources on which people depend. If these relationships are not respectful, then everything will go wrong. The sickness of particular individuals, the failure of the hunt, the weather itself – these are all expressed in terms of relationship. The egalitarian individualism of hunter-gatherer societies, arguably their greatest achievement and their most compelling lesson for other peoples, relies on many kinds of respect.

The hunter-gatherer achievement, however, is not a matter of mutually exclusive qualities. Every healthy human being has the potential for all human qualities; nobody develops one kind of strength to the complete exclusion of its opposite. To this extent we are all hunters *and* farmers. The differences between one kind of society and the other are therefore to do with balance. And the imbalance has arisen because farmers have achieved such complete domination over hunter-gatherers.

Many hunter-gatherer societies have made accommodations to farmers and herders. In many parts of southern Africa and South America, hunter-gatherers have created gardens and become shepherds or farmworkers or suppliers of pots and spears. In North America, many became cowboys, and some worked as domestic servants. Modern hunter-gatherers have taken advantage of farmers to supplement their own resources, or they have looked to the new wealth of farmers to help them deal with the loss of land and the destruction of wild animals that the farmers' arrival has caused.

But in many places, in many ways, hunter-gatherers are not at ease with farming and herding ways of life. Again and again, the farmers, while using their hunter-gatherer neighbours as casual and cheap labour, complain about their 'unreliability'.

The hunters want to go hunting; gatherers like to gather. Hunter-gatherers tend not to plan and manage surplus. They need food or money now, not in several weeks' time. In the modern world, the hunter-gatherer often appears to be restless as well as poor.

The genius of hunter-gatherers is not rooted in their readiness to learn from or to work for others, however widespread these attributes may be. The compelling expression of hunter-gatherer culture lies in the balance of need with resources; the reliance on a blend of the dreamer's intuition with the naturalist's love of detailed knowledge; and the commitment to respectful relationships between people.

The hunter-gatherer within the modern, urban world is not extinct. Remaining hunter-gatherer societies continue to exhibit the qualities they have always possessed. And there are also hunter-gatherer points of view, beliefs and habits of mind within the farmers' world, inside the nations and towns that the exiles from Eden have established and from which they continue to press outwards with a nomadic imperative. Some anthropologists have pointed to the presence of people who forage at the urban community's social and economic margins – men and women, even some families, who make do on a day-to-day basis, relying on resources that are found here and there rather than earned from the routines of daily labour. This portrayal of the hunter-gatherer in the modern city accords with widespread images of hunter-gatherer destitution and landlessness. It speaks to loss rather than to achievement.

But there are more optimistic views of the hunter-gatherer in the urban setting. Indeed, there are eruptions of the hunter-gatherer mind in the farmers' world, as evidenced in the many voices raised in opposition to the unquestioned dominance of the agricultural way: protests against repressive order, bureaucratic planning, chronic inequality, patriarchal conceit, poisonous pedagogy and the denial of all that is essential to art. These are arenas in which a rival mind seeks expression and longs for its particular forms of freedom. Throughout the Western world, there are men and women who consciously choose low levels of material comfort and small numbers of children to avoid the need for large incomes, thereby pursuing lives in which they may survive without regular jobs and devote themselves instead to creative work and family life. This way of being encompasses a concern about the destruction of the natural world by the ever-growing pressures to reshape it in the interests of surplus and profit. And dissident voices within mainstream culture have long criticized the use of repression and violence both in maintaining social order and in raising children. In all these we can hear echoes of hunter-gatherer ideas and practices.

Men and women galloping on horses across the countryside in pursuit of foxes; men with shotguns who fire at pheasants, grouse or partridges driven towards them by a line of beaters; those whose wealth allows them to trawl the seas for game fish in their powerful boats – these people may claim to represent the hunter-gatherer within us all. Yet their habits and minds are fixed firm to the farming condition. Their hunting, shooting and fishing is evidence of the very characteristics that agricultural development has exaggerated, with the help of capitalist and industrial developments, to an extreme. They are suppressors rather than exemplifiers of the hunter-gatherer. They live by the systems of privilege and organization that are hallmarks of the agricultural mind.

No: the hunter-gatherers in the heartland of the exiles, living in the nation-states of farmers and in the cities farmers have built, are opponents of the dominant order. They oppose hierarchy and challenge the need to control both other people and the land itself. Consciously or not, they are radicals in their own lives. At the least, they experience the tension in themselves that comes from a longing not to plan and not to acquiesce in plans; at most, they use a mixture of knowledge and dreams to express their vision. It is artists, speculative scientists and those whose journeys in life depend on not quite knowing the destination who are close to hunter-gatherers, who rely upon a hunter-gatherer mind.

The visionaries in society are always there, and they are perhaps a part of us all. The agriculturalist mind and its economic order never quite obscure evidence of the hunters. Many people feel the strain of a way of life and a mindset that disallow all forms of improvisation and intuition. The controlling features of a life that has no place for the hunter-gatherer mind create a longing for spirituality and underpin many forms of protest, from Quaker ideals of equality to the call for deschooling society, from New-Age mysticism to concern about rainforests.

There is a common experience of something being wrong that may receive real illumination from a much more direct acknowledgement of rival forms of mind. Rival forms of mind are, of course, reducible to rival forms of society – and, in the end, to the displacement of one kind of economy by another.

Hunter-gatherers may well represent a need in all peoples to experience a profound form of freedom. But they are also within the social universe in a literal way: there are hunter-gatherer societies, along with other indigenous peoples, whose demands for cultural survival and actual territories are no less vociferous than they ever were. In every part of the colonial world, the issue of aboriginal rights is alive as an issue whose urgency and poignancy are augmented by the prospect of a final destruction.

In Australia, Aborigines contest government and industrial invasions of their lands. There have been struggles in the courts, in political campaigns and on the land itself. Settlers still want to eliminate hunter-gatherer claims to the Australian outback. Aborigine organizations protest, and in some crucial places win, their right to their own way of life, their own heritage, their own place on the earth. In 1992, the Australian High Court established a common law principle of native title to native lands.

In South Africa, the -Khomani San, the remaining Bushmen of the southern Kalahari, have managed to survive their complete displacement and dispossession, after 50 years of subsistence at the most destitute margins of South African farms and townships. With the fall of the apartheid system, these few survivors began a campaign for the return of their lands and for the right to live in whatever combination of social and economic systems they choose for themselves. In March 1999, the South African government accepted their claim and agreed to return some

50,000 hectares of original -Khomani San territory. In Amazonia, Colombian hunter-gatherers have been mapping their territory as part of new negotiations with the government, which has at last moved towards recognition of tribal rights to tribal lands.

In Canada, the land-claims era that began in 1971 has led to a number of settlements that recognize hunter-gatherer heritage and lands. The Cree of the James Bay area in northern Quebec have managed to secure the basis for a hunter-gatherer economy in a large and complex settlement of their dispute over the flooding of much of their lands to create hydroelectric dams. The Inuvialuit of the western Arctic have negotiated a settlement of their claim to aboriginal title in a large area in the Mackenzie Delta and adjacent islands. The Gitxsan and Witsuwit'en have won much greater basis for their rights in the Supreme Court of Canada. The Nisga'a have reached an agreement with Canada that gives them a core of territory and extensive rights of self-government. And the Inuit of the North-west Territories have secured from the Canadian government a territory and jurisdiction that is based on the spread of their hunting territories in the eastern Arctic. This is the new territory of Nunavut – the most ambitious attempt in the history of the encounter between colonists and hunter-gatherers to secure coexistence at the frontier.

These victories are all the result of modern political processes. They represent a small proportion of the struggles and claims that continue, in South America and Australasia, in Siberia and the US, in Australia, Africa and Canada. In all these places, there are indigenous groups who fight for their survival. The exiles from Eden, the nomads who roam the world looking for new places to settle, transform and control, must make common cause with these struggles.

15

Human activities have shaped the surface of much of the world. Farmers have effected the greatest changes, turning forests, deserts and swamps into fields and pastures. Hunter-gatherers have also shaped the world, but more subtly, intent on keeping it a place where wild plants, animals and fish can thrive. The displacement of hunters by farmers has meant less 'land' and more 'countryside'. These different ways of moving on the earth reflect the economies and societies of different kinds of human being.

The world is also shaped by stories. What people feel, know and need to pass on from generation to generation has existed in words: words that speak of how the world began, of how humans emerged in it and found both places to live and ways to deal with one another. Words are entitlement to these places. The stories of farmers, including the Creation as described in Genesis, give meaning to their ways of life. The stories of hunter-gatherers give meaning to theirs. These are different meanings, different kinds of stories. The history of the one has dominated and, to a large extent, silenced the other.

Many hunter-gatherer ways of knowing the world have disappeared, along with hunter-gatherer languages. These are rich and unique parts of human history that cannot be recovered. If the words are gone, so are the stories. A particular shape is lost forever. There are fears that hundreds more languages – many of them those of hunter-gatherers – will have disappeared within another generation. Each such case represents a harm that is inestimable: the cumulative loss of language constitutes a diminution in the range of what it means to be human.

There is, however, a story about these stories that has its own importance. The encounter between hunter-gatherers and farmers is a history of loss to one kind of society, gain to another. For hunter-gatherers, some losses cannot be compensated. But the story itself is one form of compensation. If the world can acknowledge who hunter-gatherers are, how they know and own their lands, what the encounter with farmers and colonists has meant, then some restitution can be made. An inquiry into the fate as well as the achievements of hunter-gatherers is, in this regard, part of a story that hunter-gatherers need to tell and have told. Without the hunter-gatherers, humanity is diminished and cursed; with them, we can achieve a more complete version of ourselves.

Notes

Full publication information for the sources cited in these notes is given in the references.

In addition to the specific sources I refer to in the notes that follow, I have received help and inspiration from a wide range of Arctic literature. Some of this has been popular and anecdotal, as in the case of the work of Farley Mowat (which some would say is more literary than anecdotal). I have drawn on detailed ethnography, especially in relation to the central and eastern areas of the Arctic. No fieldwork proceeds without a background of writing by others that sometimes shapes and sometimes contradicts one's own work.

There is, of course, an extensive literature dealing with many aspects of Inuit archaeology, ethnography and social organization. The work that gives a particularly wide-ranging but detailed account of Inuit life across the Arctic is that of Knud Rasmussen, who, as the child of missionaries in Greenland, grew up speaking Inuktitut, and who therefore, when he became an explorer and ethnographer, had the rare ability to speak to the peoples he met in their own language. The results of his epic expedition across the Arctic were published in the *Report on the Fifth Thule Expedition*. The work runs to several volumes; Kaj Birket-Smith wrote some, Rasmussen others. I have always found volumes 4, 6, 7, 8 and 9 most compelling; they include shamanic stories, poems and vivid accounts of Inuit elders as well as a wealth of ethnographic detail. (It should be said, however, that Rasmussen has been criticized for taking liberties with some of his sources and oddly failing to give Inuktitut versions of all the stories he includes in the report.)

Prior to Rasmussen's Thule expedition, two other Arctic ethnographers of great importance were Vilhjalmur Stefansson and Diamond Jenness. Stefansson wrote a great deal, but his book *My Life with the Eskimo* draws together much of his work in a very readable form. Also, his *Not by Bread Alone* is a remarkable exploration of Inuit (and other peoples') diets. Jenness's most important ethnography is *The People of the Twilight*, in which he describes his stay with the Copper Eskimo of the central Arctic. Jenness subsequently became an influential member of the Canadian administration of northern affairs, and was associated with plans for relocating Inuit farther south, where, he proposed, they would be able to take advantage of employment opportunities arising with new activity on the subarctic frontier. (Plans of this kind for the most part failed very quickly.)

1 In *Frontiers*, a book that looks at the web of intergroup conflicts that constitutes the early history of the southern African Cape, Neil Mostert gives many details about how both settlers and Xhosa herders thought about and behaved towards Khoihoi and San peoples. The quote I use is from comments made by John Ovington, master of the *Benjamin*, on seeing the Khoihoi of the Cape in 1693. The words of Pyrard de Laval, written in 1610, are also revealing: 'Of all people they are the most bestial and sordid… They eat … as do dogs … they live … like animals' (*Frontiers*, p108). The fate of Tasmania's hunter-gatherers is described in Mark Cocker's *Rivers of Blood*. See p115ff and p127 for the quotes I use.

The literature reveals many voices that concur in their suggestion that the 'savages' Europeans encountered during the early years of exploration and colonization were not quite human. Of course, many societies and nations dehumanize their enemies and competitors. Yet to say that men, women and children who have languages, beliefs, clothing, implements and art are nonetheless something other than human is both strange and troubling. When aboriginal women are also the objects of sexual desire and the bearers of colonists' children, the suggestion that they are not human appears to be as ridiculous as it is grotesque. All the more striking, therefore, to find it occurs in so much commentary by settlers and explorers as they arrived in new frontiers.

There are, of course, some counterexamples, among which are the observations in G. F. Lyon's *Private Journal* about the Inuit of the Igloolik area, whom he visited often when icebound in north Hudson Bay in the 1820s. Lyon was impressed in many ways by the people, whose snow-houses he visited, and who, in turn, visited Lyon's ship. Yet even in these sympathetic and seemingly accurate reports, there are troubling descriptions of the Inuit visitors' taste for sugar and salt and their reactions to liquor.

2 An account of the Las Casa/Sepulveda debate is given in Lewis Hanke's *Aristotle and the American Indians*. There is also an article on the subject in Thomas Berger's *A Long and Terrible Shadow*.

3 Mexica (or Aztec), Maya and Inca societies constituted the 'high civilizations' of the Americas. The Mexica world – including its use of human sacrifice – is described by Inge Clendinnen in her book *Aztecs*. Marvin Harris's *Cannibals and Kings* documents, and speculates about the rationales for sacrifice and cannibalism in the region. It is important to emphasize here again that Aztec society was very distant from hunter-gatherer modes of life.

4 Thomas Hobbes's famous dictum about life being 'nasty, brutish, and short' comes from his *Leviathan*, first published in 1651. For a compelling account of how the philosophical views of both Hobbes and John Locke related to the development of capitalism, see C. B. Macpherson, *The Political Theory of Possessive Individualism*.

5 Vico, writing in the 1740s, sought to create a philosophy of history and a theory of knowledge in which the artefacts of humans (from chairs to social and economic events) could be known with certainty – unlike the creations of God (i.e. the natural world), which could not thus be known. His speculations about a 'savage state' rather surprisingly include a theory about a transition from hunters to herders, representing a shift from 'bestial wandering' to a reliance on pasture. Vico's work is cited in Alan Barnard's essay 'Images of hunters and gatherers in European thought'.

The idea that human beings are born free and then enslaved by the evils of civilization is associated with Rousseau and the romantic tradition within the Enlightenment school of philosophy. But Hugo Grotius, the Dutch theorist of law, noted in the early 1600s that 'foragers' lived 'without toil', and Engels, writing in the 1880s, saw in hunter-gatherer systems evidence of both 'primitive communism' and matriarchy. In this regard, Engels's *Family, Private Property and the State* stands as a fascinating attempt to use anthropology as the basis for a social critique of 19th-century society. For a review of the history of this issue, see Alan Barnard, op. cit., pp375–383. Barnard also quotes Montesquieu's 1748 *De l'esprit des lois*; Hegel, writing in 1820; and Marx, writing in 1857 (pp378–379).

The question about where a theory of hunter-gatherer society (albeit not always thus named) arises in European intellectual history can perhaps be answered by examining the purposes such a theory may have served. In his paper 'On the origins of hunter-gatherers in seventeenth-century Europe', Mark Pluciennik of the University of Wales speculates about these purposes (see note 20).

6 Ralph Standish is quoted in Neil Mostert's *Frontiers* (p108). Mostert also quotes a Reverend Terry, who wrote in 1616 of the Khoihoi that they were: 'Beasts in the skins of men rather than men in the skins of beasts' (pp107–108). In fact, Khoihoi were pastoralists, relying on herds of fat-tailed sheep; early settlers, however, did not make a significant distinction in their judgement of degrees of human development between Khoihoi sheep herders and San (or Bushmen) hunter-gatherers. Mostert writes very compellingly of the relationships between early settlers – black and white – and the San, describing both the degree of dependence that settlers had on San knowledge and the low level of humanity to which the San were nonetheless consigned. He quotes the South African historian George MacCall Theal as representative of his time in observing that Bushmen habits 'were not much more elevated than those of animals', and that it was difficult to conceive of a human being 'in a more degraded condition' (pp31–32).

7 The Trudeau government's position on the place of Indians in Canadian society was first set out in a 1969 white paper, issued on the authority of the then minister for Indian Affairs, now Canadian prime minister, Jean Chrétien. The white paper argues that there should be a gradual ending of treaty rights of Indians, and that the dissolution of their reserves and related special status would be an appropriate and necessary form of development. This position caused outrage throughout the country's aboriginal communities, mobilizing a newly radical form of First Nation politics. The Calder case entered the courts in the same year, reaching the Supreme Court (after comprehensive defeats in the two lower courts) two years later. The shift in Trudeau's policy may be said to have resulted from the combined impacts of the new Indian politics and the Supreme Court judgement.

In fact, the Calder case was not the first such consideration of aboriginal rights in Canada. Its significance lay in the Supreme Court's split decision – the sign of a changing legal atmosphere. The sequence of events, and the uses of evidence, that determined this atmosphere are set out in Dara Culhane's *The Pleasure of the Crown* (see especially pp72–89). Culhane quotes the Canadian historian Peter Kulchyski, who has observed that the legal forum is a strange and even incoherent one for resolving issues of rights. Kulchyski comments that the history of the court cases is often one of 'losses and gains, of shifting terrain … a history where the losers often win and the winners often lose' (Culhane, p73).

8 The modern case that most clearly defined the test for aboriginal title and right in Canadian courts was *Baker Lake* v. *the Crown.* This case also led to a view that aboriginal people could only claim rights to resources they actually use. This created uncertainty about the question of resources people did not know about in their territories, for example, minerals, oil and gas. The judgment in Baker Lake suggested that if people did not know about their assets and were therefore not using them, they had no rights to them. The Delgamuukw case, which reached the courts in 1994 and was decided in 1997, has led to a redefinition of the tests, and recognizes much more of indigenous peoples' potentially inherent rights in all aspects of their territories, including the potential for development without reference to particular use. One of the issues that Degamuukw settled was the depth of time that evidence must show. It ruled that for title, the relevant date was 1846; for rights (i.e. use and resource, including fishing, hunting and gathering), the date should be time of first contact with Europeans.

The St. Catherine's Milling case of 1885 is an early judgment that has been brought to bear in modern land-rights cases. It is important because it speaks to which agency has the right to extinguish aboriginal title, the federal or provincial Crown. It also speaks to the consequences of extinguishment. It is not a case, however, that establishes a precedent for any protection of aboriginal rights or titles to either land or resources.

The earliest case that does address the nature of aboriginal rights, and which also bears on modern cases, was decided in Southern Rhodesia in 1919. Judgment in this case introduced the notion that you could have aboriginal people who roam and have no society, and therefore led to the requirement that native litigants show they have an organized society. It was here that the idea that human beings can be placed at different levels of an evolutionary ladder entered into modern jurisprudence, with the attendant notion that some peoples are so low on this ladder – as evidenced by their way of 'just wandering around' – that they have no rights to lands or resources. (See Dara Culhane's *The Pleasure of the Crown* for these and other cases, especially chapter 6.)

9 The 'organized society' test depends on the idea that some humans are not humans. This is social-scientific nonsense, of course, and originates in an attempt to justify expropriation on racial or cultural grounds. At the end of the 20th century this was given the name 'ethnic cleansing' – a new term for what many hunter-gatherers have long experienced.

10 Biologists spend a great deal of time testing the intelligence of many species, from rats and pigeons to chimpanzees and parrots. Many forms and levels of intelligence are described as a result of this research. But biologists who assess the achievements of animals in experimental tests, or measure their speed and effectiveness at learning new skills, are not creating models of internal linguistic abilities. It may be that some human actions that we believe arise from consciously made decisions, processed in language, are more directly controlled by our genetic hard-wiring than we would like to admit – though this is an area of ongoing contention. The central point is that what happens with language, and therefore in the mind, pertains to a uniquely human form of intelligence.

11 The observation on apes is from Derek Bickerton's *Language and Human Behaviour*, p7. The quote about noises from our mouths is from the first page of Steven Pinker's *Language Instinct*.

12 A question arises in relation to the spread of humans across the world: what was the process that resulted in so many *different* languages? Linguists have identified correlations between the length of time a society is isolated from its neighbours and the evolution of a distinct language. By analysing vocabulary and grammar, it is possible to analyse links between peoples and even sequences of movement. The human geographer James L. Newman has suggested that farming, by causing people to settle in scattered but definite places, increased the degree of isolation between communities. He uses this to explain the multiplicity of agricultural languages in, for example, much of Africa (see his *Peopling of Africa*, especially p4).

Obviously hunter-gatherers settled in large territories giving rise to a language map with accordingly large areas in which people speak the same language. But where one hunter-gatherer society's territories meet those of another hunter-gatherer society, languages differ – sometimes at the level of dialect, sometimes at the level of language family. The boundary between Athabaskan and Algonquian speakers in subarctic North America, for example, suggests deep conservatism with regard to language, despite closely related economic systems. Similarly, a map of languages for the North Pacific Coast would show great varieties of languages in relatively small regions. The region that came to be California once contained approximately 80 different aboriginal languages. By comparison, the spread of Indo-European languages is a homogenizing process resulting from farming. It may be that when it comes to the variety of human languages, Newman has attributed to agriculturalists some of the features of hunter-gatherers.

13 The quote comes from Desmond Clark of the University of California at Berkeley. It is cited in a summary of the findings pertaining to *Homo erectus* and language in Robin McKie's *Ape/Man* (pp82–84). McKie reviews the evidence for the links between language and *Homo Heidelbergiensis* on pp122–124. In fact, the evidence he gives of humans who probably had language comes from European sites. Much related evidence argues strongly in favour of the view that these language users in Europe came from somewhere in Africa, and that their dispersal was itself a result of speech. This means that the date of *Heidelbergiensis* is a very late date to use in pinpointing the beginnings of language. The matter remains unresolved, but it would seem reasonable to say that our ancestors made the evolutionary step necessary for language at least 1 million years ago.

14 The process by which human beings acquired language is bound to involve speculations about the nature of evolution, the structure of the human brain and the functional advantages of language itself. The science that pertains to these things is constantly evolving. An account of the evidence, and the state of the relevant scientific art, is to be found in Steven Pinker's *Language Instinct*. Pinker reviews the results obtained by experts who have attempted to teach apes to use language (see pp335–349), revealing how unsuccessful these attempts ultimately are as language learning, then considers evolution and the probably development of a hard-wired faculty for language in human brains (p349ff). On the question of how long it took for humans to evolve language, he notes: 'We expect a fade-in, but we see a big bang' (p343).

15 Anthony Traill made the observation that San speakers are 'the acrobats of the mouth'. His essay '*!Khwa-Ka Hhouiten*, The Rush of the Storm' offers many insights into both the nature of San Language and the causes of language loss. I am grateful to the ethnolinguist Nigel Crawhall for details about the sound elements in different languages (personal communication, 1999).

16 Noam Chomsky's work on language began in the 1950s and continued into the 1970s. The quotes here come from *Reflections on Language*. These passages are quoted at greater length in Steven Pinker's *Language Instinct*, pp22–23.

17 This issue is discussed in Steven Pinker's *Words and Rules* (p198), where he cites the work of Arnold Zwicky, James Morgan, Lisa Travis, J. Tooby and Irven DeVore. For Pinker's comments on grammar learning and identical twins, see *Words and Rules*, p203. For Pinker's concluding remarks, see p210.

18 Lévi-Strauss first wrote about the Nambikwara in the 1940s. He contributed an essay to volume 3 of the 1948 *Handbook of South American Indians*. The first edition of *Tristes Tropiques* was published in 1955; it was translated into English as *A World on the Wane*, first published in 1961. *The Savage Mind* (*La Pensée Sauvage*), published in French in 1962 and in English in 1966, is the book of his that had the most widespread impact on European intellectuals. Lévi-Strauss's work on kinship and totemism, especially *Les Structures elémentaires de la parentée* and *Totemism*, published in 1962 and 1963, respectively, examined core questions of anthropology.

19 The Lévi-Strauss version of the myth, which takes place in the Nass Valley in Nisga'a territory (though Lévi-Strauss identified it by the broader term Tsimshian, now used to refer to the language family of the region), was drawn from written accounts. His analysis of the myth, 'The Story of Asdiwal', was published with an accompanying essay by Edmund Leach, in which Leach gave himself the task of explaining and celebrating structuralism to English anthropologists. Neither Lévi-Strauss nor Leach ever did fieldwork in the region.

20 In his paper 'On the origins of hunter-gatherers in seventeenth century Europe', Mark Pluciennik of the University of Wales suggests that the new science of political economy divided human society into hunters, herders and farmers as part of a need to rationalize and justify individualism, inequality and the unquestionable obligation of labour. Natural laws were sought that would show that certain kinds of individual owed service to society but could not expect to be an equal member of it. Pluciennik suggests that the purported 'laziness', 'ignorance' and 'inferiority' of 'savages' was useful to this project because it laid a 'natural' foundation for hierarchy and the possibility of fundamental differences among people.

He also suggested that these categories – hunter, herder and farmer – are contingent and heuristic: they were invented to meet a particular intellectual and political need, and are not grounded in sociological or anthropological reality. A difficulty with this reductionist account of the categories lies in the extent to which they are to be found in other languages and times. At the Cambridge conference where Pluciennik put forward his view that the categories belonged to 17th- and 18th-century social theory, not to reality, James Woodburn pointed out that the same categories are to be found in the Bantu languages of southern Africa, with a provenance far from the political economists of 17th-century Europe. Woodburn also observed that these categories correspond to what people can most readily observe. Hence it is not surprising to find that a distinction between hunter-gatherers and the herders or farmers who are their neighbours is of great importance to both the hunter-gatherers and the agropasturalists themselves.

21 The history of peasant life in Ireland has yielded a number of 'traditions'. In reality the domination of peasant families by landlords seeking to maximize rents created the Ireland that is most often said to be 'traditional'. This is the peasant life described in Conrad Arensberg's *Irish Countryman*, then in Conrad Arensberg and Solon Kimball's famous *Family and Community in Ireland*. This particular peasant society, whose features made it so vulnerable to potato blight, developed in the period between 1700 and 1850. An ancient Irish society, reaching back to Erse myths and the 'golden age' of Irish ruling families, was destroyed by British invasion, beginning in the 13th century and ending with Cromwell's conquest of Ireland in the mid-17th century. I discuss Arensberg and Kimball's sociology in *Inishkillane*, pp4–7.

The literature of Ireland is not to be reduced, of course, to a reflection of any single aspect of Irish (or any other) history. Yet there is a connection between the moods of much Irish writing and the successive transformations and disasters in the history of the country's peasantry. This idea is something I use throughout the text of *Inishkillane*, setting literature alongside sociology.

22 James Woodburn's summary of attitudes to hunter-gatherers in southern Africa is in his essay 'Indigenous Discrimination'. There Woodburn details a set of negative attitudes that their neighbours appear to hold towards hunter-gatherers, then goes on to identify reasons for the discrimination. This includes the *appearance* of hunter-gatherers in the eyes of agriculturalists or pastoralists, with a related identification of hunter-gatherers with the wild, and the apparent absence among hunter-gatherers of institutions of authority and social control. Woodburn also cites evaluations of hunter-gatherers that are ambiguous or even positive, identifying the extent to which they are believed to have exotic powers; but he adds a fascinating observation about the extent to which in Africa and many other places, 'there is a fear that those who are weak and impotent have mysterious supernatural powers which threaten those who exercise power. Power holders tend to be ambivalent about their right to power, wealth and prestige and they fear that resentment of those who lack power, wealth and prestige may mysteriously threaten their health, well-being and prosperity.' He adds that hunter-gatherers can, at times, use this fear to redress some of the political imbalance between themselves and others. Other writing by James Woodburn that bears on these issues includes the introduction he co-authored with Alan Barnard to *Hunters and Gatherers* and his essay 'Egalitarian Societies'.

Environmental and Health Benefits of Hunting Lifestyles and Diets for the Innu of Labrador

Colin Samson and Jules Pretty

Background to the Sedentarization of the Innu

The Innu are Algonquian-speaking people of the Labrador-Quebec peninsula. For some 8000 years, they and their ancestors were permanent nomadic hunters ranging over an area the size of France. In the boreal forests and tundra of the interior of the peninsula they hunted caribou, including the vast George River herd, as well as bear, marten, lynx, fox, beaver, otter, muskrat, partridges, ptarmigan, ducks, geese, several species of fish and occasionally seals in the coastal bays. Archaeological evidence suggests that the ancestors of the Innu also had a maritime element in their economy and that the ancestors of the Innu moved inland to concentrate on caribou hunting following Inuit expansion to the Labrador coast around 1300 (Loring, 1997, 1998; Loring and Ashini, 2000; Loring et al, 2002).

But from the 1600s onwards, the Innu way of life was gradually reshaped following contact with European colonists and by subsequent pressures placed upon it by missionaries, fur traders and the Canadian state (Leacock, 1954, 1995; Henriksen, 1973; Samson, 2003a). In the mid 20th century, the Indian Act was implemented in Quebec and those Innu coming to trade at the various posts, which eventually became villages, were registered and officially regarded as domiciled there. In Labrador, the focus of this study, the provincial authorities initiated an aggressive assimilation campaign soon after Newfoundland joined the Canadian confederation in 1949. This resulted in the sedentarization of Innu hunting families in the late 1950s in the village of Sheshatshiu, on the opposite shore to the North West River trading post on Lake Melville in Central Labrador, and in Davis Inlet (or Utshimassits) on Iluikoyak Island, across from the old Davis Inlet trading post on the north Labrador

coast in 1967. Davis Inlet is now abandoned following a further relocation of the Mushuau (or 'tundra') Innu to Natuashish on the mainland in 2003. Today, there are some 18,000 Innu in Labrador and Quebec, of whom some 2100 live in the two villages in Labrador (Indian and Northern Affairs Canada, 2005a, 2005b).

Sedentarization inevitably undermined the relationship of the Innu to their hunting culture, because mobility was central to its efficiency (Loring, 1997, p198) and the land provided the basis for their social, economic and religious ideas and practices. As with other indigenous people across North America, 'breaking the Indian relation to the land had concrete as well as symbolic significance' (Rogin, 1987, p155). The vast interior of Labrador-Quebec suddenly became free of mobile populations. Severing the relationship between people and land was then an important precursor to natural resource exploitation and extraction for timber, energy and minerals (Samson, 2003a, pp86–96). In addition, placing the Innu in villages also had vast symbolic value, as the authorities saw it as a measure of their integration into Canadian society. At the centre of the sedentarization project was the conversion of the Innu not simply to Christianity but to a Western and modernist worldview. Formal schooling was central to the goal of making Innu think more like Canadians and, it was thought, eventually helping them accept the change from subsistence hunting to lives of paid wage labour.

However, to date no reliable source of wage labour has been found for the Innu, and most families survive on welfare payments. With the exception of a few individual political leaders, Innu are at best peripheral to all decisions about economic development and the environment in Labrador. Most employed Innu work in the government-created institutions of the villages. Only a handful work in Goose Bay or in resource extraction industries, such as the Voisey's Bay mine, 75km north of Davis Inlet. These latter jobs primarily offer sporadic and temporary employment. Similarly, experiences of the Innu around Bersimis (Charest, 1982, pp421–422) and Schefferville, both in Quebec, indicate that only a handful were employed in hydroelectric and mining projects respectively, and then only at low levels on below-average salaries.

Instead of employment, sedentarization has been accompanied by an increase in heavy drinking, suicide, solvent abuse and sexual abuse (Samson et al, 1999; Samson, 2003b). Ironically, much of the employment for the Innu is now in non-professional jobs in clinics, homes, shelters and treatment programmes in the villages. The advent of village-based social pathology among peoples immersed in what had hitherto been a relatively stable and mobile society is similar to changes recorded in other northern native communities subject to similar pressures (Brody, 1981; Bussidor and Bilgen-Reinart, 1997; Boothroyd et al, 2001; Inuit Tapiiriit Kanatami, 2004). Sedentarization policies, motivated by a mixture of desires to assimilate mobile groups and clear lands for agriculture and resource extraction, have occurred in many other places, including Australia (Trudgen, 2000; McKnight, 2002), Botswana (Gall, 2002; Olmsted, 2004) and Mongolia (Humphrey and Sneath, 1999) with similarly negative consequences for the populations involved. The loss of self-esteem, manifested in ubiquitous alcohol abuse, child gas sniffing and suicides, has had a profound effect on the Innu and their way of life. More than two decades ago, Brody (1981, p72) described the pathology of similarly situated aboriginal communities elsewhere in Canada: 'many northern reserves appear to be grim and even hateful little places, clusters of houses crowded together by planners in order to achieve economies of administration and services… Such compression of a people distinctive for their free roamings through unbounded forest is bizarre and painful.'

The feeling of loss experienced by the Innu is bound up with a tension that has built up between the past life in the country and the present life in the villages. The nomadic hunting way of life is often regarded as strenuous and sometimes demanding to the point of life-threatening, but it is healthy, vibrant and connects people to a core of their cultural and environmental identity. Typically, hunting families are spread out across a vast expanse of territory, and so have little aggregate impact on resources. Settlements, on the other hand, are seen as permeated by misery created by alcohol, sexual abuse, family rivalries, boredom and the physical confinement to a relatively small area. Because the village is now the site of so many recent personal tragedies the feeling of loss is magnified, especially among the generation that have known both country and village life. The remarks of Kanikuen Penashue, a resident of Sheshatshiu, are typical: 'the problem is that we are so scared because the things that exist today are not explainable. They are so new to us. The whole world changed right under our feet. We are lost.' (Innu Nation and Mushuau Innu Band Council, 1993; see also, Innu Nation and Mushuau Innu Band Council, 1995, pp24–41). Local settlers at North West River have also observed a change in the Innu from their confidence and generosity in the country to their trauma and suspicion of whites after sedentarization (Plaice, 1990, pp74–87).

The primary response of the Canadian government has been to fund village-based solutions such as medical and quasi-medical establishments, emergency medical evacuations to Newfoundland, and housing, sports and building infrastructure (especially for alcohol programmes, clinics and homes). The relocation of the Mushuau Innu from Davis Inlet, where they endured life in shacks without sanitation and running water from 1967 to 2003 to the new C$152 million village of Natuashish can also be seen as part of these efforts (Indian and Northern Affairs Canada, 2005b). The Labrador Innu Comprehensive Healing Strategy implemented by the Canadian government is almost entirely 'community-based' (see Treasury Board Secretariat, 2004). Despite these efforts, social pathology has continued to worsen since the move with four suicides in the first year and with the discovery that 35 per cent of students at the Natuashish school suffered from Foetal Alcohol Syndrome (Philpott et al, 2004). While some government policy reactions to the visible health crisis among the Innu have been welcomed, by ignoring the importance of Innu connections to the land, they fail to address some of the root causes of that crisis.

Our objectives in this paper are to examine the biological and environmental underpinnings of this crisis, and use them as a basis to show how country-oriented solutions might offer more hope of stemming the physical, psychological and cultural decline of the Innu. We make our case for a country-oriented shift in policy by arguing that two transitions have been fundamental to recent Innu history.

Firstly, a nutrition transition can be discerned in the abrupt shift from consumption of wild foods to processed foods. This is paralleled by a physical activity transition, from regularly active and strenuous exercise to much less demanding set of activities in the village. We investigate these transitions through both historical sources and interviews with Innu, and then explore how such changes have impacted upon health. We also compare nutritional properties of country foods with those of foods consumed in the village, as well as compare activity patterns in the country and in the village. We then use medical and environmental data to examine how the new junk food diets and lack of exercise are affecting the health of the Innu. Finally, we look at how practical policy changes and economic activities such as those being promoted by the Tshikapisk Foundation (2004), an association of Innu hunting families, could be put into effect to restore hunting activities and address some of the manifold health problems of the Innu. The research is based on the fieldwork of one of the authors (CS) with the Innu since 1994, and joint research since 2002, involving interviews, observations and data collection in Sheshatshiu and in the country at Kenemau.

The Nutrition Transition

The indigenous relationship with the land

A key to understanding the crisis of the Innu lies in setting their recent experiences in the villages in contrast to their historical and continuing connections with the land. In the country, the Innu experience daily connectedness and respect for nature, and the closeness of families and communities. When Innu look at the country, they do not just see animals, trees and water. Like many other indigenous peoples, they see places with stories, they locate events, they see ancestors wandering the land, they see past and present intimately linked, they see tracks and signs, and nature tied together with them (Brody, 1981; Lopez, 1986; Basso, 1996; Cruikshank, 1998; Nuttall, 1998; Posey, 1999; Clayton and Opotow, 2003; Folke, 2004). But when Canadian and Newfoundland policy makers turned their attentions to Labrador, they instead saw the economic value of timber, of reservoirs for hydroelectricity, of iron ore and nickel in the rocks, and of the wildlife that needed protecting (Samson, 2003a, pp96–111).

This core difference in values is critical. For the Innu, to destroy a part of a connected system is eventually to undermine the whole. In the country, the Innu feel they have much greater autonomy and freedom. They are able to choose when to hunt and when to rest. Their decisions affect the land and its resources, and their knowledge accrued over hundreds of generations of observation and experimentation determines their success. By contrast, life in the village is quite different. Because the economy required to support wage labour never materialized as the provincial authorities had earlier promised (Samson, 2003a, pp96, 142–147), there are few secure jobs for Innu, and thus a dependence on welfare has emerged with little opportunity for self-reliance or self-determined life choices. A significant component of this change involves food. In the country, the Innu were self-reliant in providing for their sustenance. Contacts with missionaries and traders brought firearms, tea, flour and tobacco, but because they were relatively autonomous until sedentarization, the Innu diet largely consisted of wild meat, fish, waterfowl and berries (Samson, 2003a, pp127–142).

The transition to processed foods

The nutrition transition is a well-established phenomenon in both industrialized and developing countries (Popkin, 1998). In almost all of these industrialized and developing country contexts, people have been largely dependent on the produce from agriculture for several thousand years, and the nutrition transition has involved a change from one diet based largely on foods from domesticated crops and animals to another with similar derivation but with increased processing. For the most recently settled hunter-gatherer societies, such as the Innu and other indigenous peoples of Canada, their transition has occurred directly from wild foods to modern refined (and often junk) foods.

In the Arctic and Subarctic regions, indigenous peoples' diets have changed from foods that are typically nutrient-dense, with high levels of protein and fat (especially omega-3 fatty acids), and vitamins and minerals (e.g. vitamin C, selenium), but relatively low levels of carbohydrates, to diets high in carbohydrates and saturated fats and low in essential nutrients (McGrath-Hanna et al, 2003, pp230–231). Importantly, these changes are on the whole very recent, with northern peoples such as the Innu and Eastern James Bay Cree (Delormier and Kuhnlein, 1999, p182) still engaged in some hunting activities while domiciled in villages. Hence, their diets consist of both country and modern, largely processed, foods. While country foods can remain a significant part of the sustenance and nutritional intake of some northern peoples, the diet that has become the norm over recent decades is one that is deficient in many of the healthy properties of food. A survey of seven northern aboriginal communities in the 1990s characterized this pattern as being low in fruits, vegetables and dairy products, high in sugar, fat and saturated fat, and consisting of intakes of calcium, magnesium, folate, vitamin C and vitamin A that do not reach recommended doses (Lawn et al, 2002, p10).

Amongst Innu *Tshenut*, there is a widespread view that store bought food is both unhealthy and makes people ill. This was evident almost as soon as the Innu were sedentarized in the 1950s and 1960s when Father Frank Peters (1972, pp10–11) quoted Innu at the new Davis Inlet village as feeling hungry after eating processed food, and feeling that chicken, pork and beef were not as substantial as caribou meat. At the same time, he also noted the rapid deterioration of the teeth of the population, a condition he attributed to the sudden availability of sweets and soft drinks in the store. Other observers noted exactly the same unfavourable comparisons being made between store and country food at the time (Henriksen, 1977, p4), and as late as the 1990s, many Innu believed that the foods in the store were also adulterated, stale and unsafe to eat (Innu Nation and Mushuau Innu Band Council, 1995, p39). By contrast, a visiting physician reported that people in the country were remarkably healthy, with very few cardiovascular or lung problems, and good dental health (Sarsfield, 1977). The major causes of mortality were trauma from accidents and infant illnesses.

These observations of the worries Innu had about store food in the early days of Utshimassits are backed up by the reminiscences of people who remember the times of transition from permanent country living to semi-sedentary village life. Some believed that their children would starve because store food is not as good for them as caribou, beaver and porcupine (Elizabeth Penashue, interview, 1994). Others observed high numbers of children getting sick in the community (Shimiu Penashue, interviewed 1995) and other Innu maintain that the food purchased in the stores does not taste good (Pien and Lizette Penashue, interviewed 1997). These sentiments were shared by Mary Adele Penashue (interviewed 2003), who remarked, 'I have strange feelings when I'm in the house eating store-bought food… It's making us sick and weak, this fast food' Despite these views, store-bought processed food has become increasingly dominant in the diets of Innu in the villages, and is starting to be preferred by the younger generations.

Nutritional content of country and store foods

Once there has been a lifestyle change brought about by sedentarization, then indigenous people have no constant access to country food throughout the year, and so come to rely on store-bought food derived from distant agricultural systems. This becomes a health problem as hunted and gathered foods are very different in nutrient content and density than store-bought foods. Table 4.1 shows the energy, protein, fat and key vitamin content of eight types of wild meat and fish compared with eight domestic meats available in local shops. These data show energy and protein levels similar to those measured *in situ* for the Cree (Berkes et al, 1995). Table 4.2 contains details of the recommended daily allowances (RDAs) for adults and children, and shows that RDAs for minerals, vitamins and energy can be reached with relatively modest quantities of country foods.

For this sample of 16 foods, store food has 75 per cent more energy content than country food (1.26MJ $100g^{-1}$ compared with 0.72MJ $100g^{-1}$), 37 per cent less protein (20.9g compared with 28.7g), and more than four times as much fat (23.2g compared with 5.7g), of which 8.7g are saturated fats. These saturated fats are known to be an important risk factor in coronary heart disease and also contribute to the addition of body fat.

Country foods also contain more iron (4mg $100g^{-1}$ compared with 1.68g in store foods). Iron deficiency is now a recognized problem for an increasing number of mothers and children worldwide following the adoption of modern diets (ACC/SCN, 2000). There is more than three times the vitamin C in this sample of coun-

try foods, 50 per cent more riboflavin, 67 per cent more niacin, though less than half the thiamine. These high concentrations of vitamins in country foods are important for hunters such as the Innu with little or no cereals or vegetables in their traditional diets. Some country foods are very high in certain vitamins – ptarmigan, for example, has ten times as much niacin than other meats and fish (Mackey, 1987), and caribou and duck are high in thiamin. A variety of berries are important sources of vitamin C, even though only relatively small amounts are consumed as a result of the short growing season. Clearly, these country foods were once able to supply the necessary macro- and micro-nutrients to ensure adults and children remained healthy over thousands of years.

How do these foods compare with a typical 'junk' food meal of the sort now increasingly available to the Innu and other indigenous peoples? One typical meal of a cheeseburger with French fries, each of some 170g in weight, would supply 52g fat (of which 16g are saturated), 31g of protein, and a total of 4.29MJ (35 per cent of the daily recommended total for adult males and 47 per cent for women). By contrast, a 340g meal of caribou meat would supply 15g of fat (of which 5.8g are saturated), 101g of protein, and 2.37MJ (20 per cent of male and 26 per cent of female RDAs). A similar meal of salmon provides 25g of fat, 93g of protein, and 2.62MJ of energy, and of beaver 23.7g of fat, 119g of protein, and 3.01MJ of energy. The nutritional value of hunted, fished and gathered foods is magnified still further because almost all edible parts of foods are consumed by northern peoples. With the caribou, for example, all the organs are eaten, as well as bone marrow, both of which provide important sources of fat from an animal that is typically very lean (Tracy and Kramer, 2000, p48).

A variety of studies of indigenous groups across the Canadian Subarctic have recorded how much country food is consumed after the lifestyles of aboriginal peoples were shifted from being nomadic to settled. These vary from a low of 52kg per person per year in Manitoba communities, to 96kg yr^{-1} for Inuit in Labrador, 115kg yr^{-1} for the James Bay Cree, 146kg yr^{-1} for Omushkego Cree in Ontario, 221kg yr^{-1} for groups in the Keewatin region, and 285kg yr^{-1} for the Inuit of north Quebec (Mackey and Orr, 1987; Wein et al, 1991; Berkes et al, 1995a). These amount to a daily consumption of between 140g and 781g of country food. Some 200g of country food supplies the recommended daily protein requirement for adult males, while 175g is sufficient for adult females (see Tables 4.1 and 4.2). Clearly, continuing to consume country food will be good for the physical health of Innu and other northern peoples. The hunter-gatherer nutritional regime is the oldest human diet and is well-suited to human physiologies (Eaton and Eaton, 1999, p449).

The decline in country food consumption

Country foods still remain a part of the diets of the Innu and other northern peoples. Among the Cree, for example, 29 species of wildlife are still eaten, each with 2–11 edible parts, with fish and birds the most consumed in summer, and large and small mammals the most important in winter (Delormier and Kuhnlein, 1999). During summer, about half of the fat consumed by women comes from country foods, with Canada goose the most important single source (14.3 per cent). In winter, though, only one of the top 20 sources of fat was a country food (goose again), with the top source now french fries (9.6 per cent of total fat). Among the Cree, Chipewyan and Metis peoples around Buffalo National Park, Wein et al (1991) estimated that households ate country foods six times per week during the late 1980s.

Wagner's (1986) study of ten reserve communities in Manitoba indicated that the harvest size and diversity of country foods depended on the local availability of wildlife habitats and cultural preferences. Harvests were greater in the more sparsely populated northern communities. By comparing documented records for 1912–1914, it was clear that consumption of country foods had declined (Table 4.3).

Table 4.3 *Changes in annual household consumption of country foods between 1912–1914 and 1983–1984*

	Central Quebec 1912–1914 *(numbers of each animal; fish in kg)*	**Manitoba 1983–1984** *(numbers of each animal; fish in kg)*	**Changes (%)**
Moose	0.8	0.54	–32.5
Caribou	2.5	0.07	–97.3
Beaver	94.3	5.6	–94.1

Rabbit	5740	3	–99.9
Duck	135	15	–88.9
Fish (kg)	7215	78	–98.9

Source: Wagner, 1986

Using a caesium tracing method, Tracy and Kramer (2000) found that caribou consumption in northern Canada had declined by 80 per cent in 11 communities from 183g day^{-1} in 1967–1968 to 35.1g day^{-1} in the 1990s.

Similar declines in country food consumption have been recorded amongst the Inuit of Greenland (Pars et al, 2001). In the north-west, country foods (including here seal and whale) provided 54 per cent of daily energy intake in 1952, but this had fallen to 25 per cent by 1991. Once again, younger people consume fewer country foods, as do those in households resident in larger towns compared with those in villages. The youngest group consumed the most soft drinks, fruit syrups, and fruit and vegetables. Most studies have found that young people now consume less country food than elders (Wein et al, 1991; Tracy and Kramer, 2000, p46), and that there have been declines in consumption over time. Delormier and Kuhnlein (1999) found that there had been a decline in use of traditional foods among the Cree of Quebec, particularly by the younger generation. Berkes et al (1995a, 1995b) found similar changes amongst the Cree of northern Ontario. An Indian and Northern Affairs Canada (INAC) nutrition survey (Lawn et al, 2002, p4) found that among adults over 45 in Inuit communities in Nunavik (northern Quebec) about a third of energy was obtained from country foods, compared with only 22 per cent among younger women and 18 per cent among younger men. Older people were also reported to be eating much less junk food than their younger counterparts.

There are few data on changes in consumption of country foods by the Innu over time (Usher, 1976; Mackey and Orr, 1987). Usher (1976) found that the major source of food and income in northern Labrador came from harvesting country foods. In the 1980s, Mackey (1987) indicated that 30–65 per cent of the Innu in Labrador continued to spend the autumn and/or spring months in the interior hunting, trapping, fishing and gathering. This has fallen dramatically since the withdrawal of funding for the Outpost programme, which enabled Innu families to spend several months a year in the country.

Health consequences

Changes in diet have had severe and costly public health consequences in most industrialized countries (CDC, 1996; Ferro-Luzzi and James, 2000; Eurodiet, 2001; Nestle, 2002). One of the most serious consequences of poor diet is the emerging obesity epidemic, the costs of which are some US$117 billion per year in the US, compared with US$97 billion for smoking (Kenkel and Manning, 1999). The Eurodiet (2001) study has also concluded that disabilities associated with high intakes of saturated fat and inadequate intakes of vegetable and fruit exceed the cost of tobacco use. It is further acknowledged that sedentary lifestyles are a major public health problem.

However, unlike most Europeans and North Americans, the Innu are still fortunate enough to have wild foods at their disposal in the vast Labrador-Quebec interior. A wide range of country foods are still consumed by all indigenous peoples in Canada, with more than 50 species of animals and birds regular in diets, including caribou, moose, rabbit, muskrat, beaver, porcupine, muskox, squirrel, lynx, fish, duck, geese, ptarmigan and grouse, together with a variety of fish, marine mammals, berries, wild rhubarb, wild onions and Labrador tea (Mackey and Orr, 1987; Berkes et al, 1995a; Wein et al, 1996). While northern peoples have been consuming these foods, the incidence of obesity, diabetes and cardiovascular diseases has been relatively low. It has been suggested that this is partly due to the high content of omega-3 fatty acids and antioxidants in the traditional diet (McGrath-Hanna et al, 2003, p230).

Although one facet of the changes occurring among northern indigenous peoples should never be taken in isolation, the public health consequences of new diets are now known to be serious contributors to a wide range of ailments. Some health problems arise from nutritional deficiencies of iron, iodide, folic acid, vitamin D and omega-3 polyunsaturated fatty acids, but most are due to excess consumption of energy and fat (causing obesity), sodium as salt (high blood pressure), saturated and trans fats (heart disease) and refined sugars (diabetes and dental caries). Diet is thought to be a factor in 30 per cent of cases of cancer in developed countries (Riboli and Norat, 2001).

While degenerative diseases such as diabetes, coronary heart disease and cancer have been relatively rare in hunter-gatherers, they are now becoming common among hunting peoples who have been sedentarized. As well as more energy expenditure and lifestyles that are more protective of the body (for example, the shorter gap between menarche and childbirth among hunter-gatherers protects against breast cancer), hunter-gatherer diets are composed of foods that are denser and more fibrous, have a high protein-to-fat ratio and lack the high amounts of sugar, salt, saturated fats and high calorie counts characteristic of many diets of people in industrialized societies. There is, therefore, much to learn from the qualities of the hunter-gatherer diet and lifestyle in terms of health promotion (Eaton and Eaton, 1999). Analysing broad epidemiological changes over time, McKeown (1988, p37) has found that diseases such as cancer, obesity, diabetes, hypertension and heart disease, as well as non-communicable diseases, are uncommon in hunter-gatherers and peasant agriculturists, appearing only when traditional ways of life are abandoned or disturbed.

Amongst Native North Americans, the result of the transition has been a rapid increase in recent years in diet-related health problems, particularly of type II diabetes, coronary heart disease and obesity (Thouez et al, 1990; Hegele et al, 1997; Story et al, 2003). This follows significant advances in reducing infant mortality, such as from 150 per 1000 live births amongst the Inuit in mid 20th century to 10 per 1000 towards the end of the century (Young, 1994). One study of Cree women in Quebec found 30 per cent with a BMI (body mass index in kg m^{-2}) of 25–29.9, and 57 per cent in the obese category of a BMI of more than 30kg m^{-2} (Delormier and Kuhnlein, 1999). Fifty per cent of the 36 women surveyed in Davis Inlet in 1992 had a BMI of greater than 30 per cent and 75 per cent of these women exceeded a BMI of 27 per cent, making Mushuau Innu women, according to these measures, the most obese of all the seven northern aboriginal communities surveyed by the INAC study (Lawn et al, 2002, p44). These are problems shared by many circumpolar peoples (McGrath-Hanna et al, 2003), and this extends to indigenous peoples across North America. Story et al (2003) suggest that 'obesity is now one of the most serious public health problems facing American-Indian children'. Hovering at an average of 25 per cent, the rates of obesity among aboriginal populations in Canada are almost twice that of Canadians as a whole (Canadian Institute for Health Information, 2004, p116).

As well as the adverse effects on physical health, there is also evidence that the change in diets for indigenous peoples may be implicated in the high rates of mental health problems suffered by these populations in recent years. Based on an extensive review of literature, McGrath-Hanna et al (2003, pp233–235) argue that the sudden shift from diets derived from hunting, fishing and gathering to those based on Western store-bought foods is an important risk factor linked with the deterioration in the mental health of circumpolar peoples. This claim is based on several lines of evidence. For example, the decline in consumption of omega-3 fatty acids has important implications for neuronal and brain development, function and health, and this has been associated with increased levels of aggression, depression, postpartum depression and suicide. Given the scientific evidence on the adverse effects of store food on the health of aboriginal peoples, it is not surprising that some indigenous groups view this so-called 'whitemans' food' as literally and symbolically polluting (Adelson, 2000, p104).

Pollution and country foods

The decline in aboriginal wild food consumption has a generational basis (Wein et al, 1991; Tracy and Kramer, 2000, p46; Pars et al, 2000; Lawn et al, 2002), and this coincides with policies of relocation and sedentarization, as well as with the acceleration of resource extraction activities from indigenous peoples' land and water resources. Not only do such activities bring with them an influx of non-native people requiring processed and frozen foods (this region is beyond the zones of agricultural production), but the industries themselves disrupt the relationships between aboriginal peoples and the lands. The decrease in country food consumption among aboriginal peoples affected by industry has been shown to be closely related to difficulties in hunting and reduced availability of animals, and to community concerns over the taste and safety of the wild foods (Loney, 1995, p233). Hence, industrialization of aboriginal lands creates both a push factor, discouraging hunting and fishing, and a pull factor, drawing people to processed foods because of fears over the adulteration of wild foods from industry (see Horton, 2004, p10A). In northern areas, processed foods have been even more attractive because of the lower costs compared with fresh produce, which is perishable, and consequently relatively expensive, especially to aboriginal families living on welfare.

The decline of country food consumption has coincided with the new threat from contaminants in country foods. For example, radioactive caesium (Tracey and Kramer, 2000, p48) and cadmium (Adelson, 2000, p84) have been found in caribou in the Canadian north. Methylmercury has been discovered in fish caught by Eastern James Bay and northern Manitoba Cree (Delormier and Kuhnlein, 1999, p182; Loney, 1995, p239), along with mercury, PCBs and pesticides in traditional foods consumed by Inuit populations in Greenland (Pars et al, 2001, p29). One of the most notorious cases of mercury poisoning affects the Ojibwa people of Grassy Narrows, northern Ontario. In the 1970s, it was discovered that a pulp mill was the source of mercury poisoning of fish caught by Ojibwa. On recent visits to the Grassy Narrows and Wabaseemong reserves, the Japanese neurologist who publicized the first cases reported that some of the residents experienced increased symptoms of the poisoning with age (Aiken, 2004). Even if the industrial developments are not as malign in their effects as this case, there are always some adverse changes to local ecosystems. Many aboriginal peoples believe that such damage diminishes the abundance of animals (Adelson, 2000, p84).

For the Innu in Labrador, environmental threats are posed by a number of large industrial projects. These include mercury in fish caught in some of the water passing through the Churchill Falls hydroelectric project, adverse changes to animal habitats (e.g. waterfowl migration patterns), water pollution from the Voisey's Bay mine, the creation of the Trans-Labrador highway, connecting Goose Bay with Labrador City, and low-level flight training (see Samson, 2003a, pp96–116). As with similar industrial projects in Canada, these also have much wider negative effects on the social fabric of the peoples themselves. The creation of hydroelectric generating projects has been found to be associated with interpersonal violence, family break-ups, alcohol and drug abuse and cultural disintegration among aboriginal peoples across Canada (Loney, 1995; Kirkness, 2000, p309).

The Physical Activity Transition

Activity transition in settled and agricultural societies

The second transition of significance to Innu physical and mental health is the activity transition. Like the nutrient transition, this has already occurred in industrialized countries, and is having a significant impact on health and well-being (CDC, 1996; Wanless, 2002; Lang and Heasman, 2004; Pretty et al, 2005a). Along with diet, physical activity is now known to be an important determinant of health and well-being. Again, human metabolism and genetic make-up have been unable to adapt to the rate of change and magnitude of changes in lifestyle that have taken place over recent decades. People in both industrialized countries and urban settlements in developing countries have become increasingly sedentary in all aspects of daily life, including during leisure time, in travelling to and from work, and during work itself. In Europe, there has been a dramatic fall in physical activity over the past 50 years with on average 2MJ less energy output per day in adults aged

20–60 years (Eurodiet, 2001). Yet the public health consequences of these changes have not, until very recently, been widely discussed or accepted (DCMS, 2002; DoH, 2004). The Eurodiet (2001) study states 'the importance of physical activity has been underestimated for many years by both doctors and policy-makers'. In the US, the report of the Surgeon General (CDC, 1996) documented similar alarming declines in physical activity and consequent increases in ill health, finding that 60 per cent of Americans are not regularly active, and 25 per cent are not active at all.

Although there is no systematic data to establish long-term trends, it is clear that lifestyles have changed in many countries, and that even leisure time is increasingly filled with sedentary behaviour (CDC, 1996). Echoing Popkin's phrase (1998), we believe that modern societies have also gone through an 'activity transition' in the past two to three generations (Pretty et al, 2004, 2005a, 2005b), with people no longer active in the workplace nor in travelling to and from work, nor during leisure time. This too has very significant health consequences for whole populations.

Yet physical activity is known to reduce the risk of dying from coronary heart disease, the leading cause of death in industrialized countries, and also reduces the risk of developing diabetes, hypertension and colon cancer. It enhances mental health, fosters healthy muscles and bones, and helps maintain health and independence in older adults (Paffenbarger et al, 1994; CDC, 1996; Hermansen et al, 2002). Compared with active people, those who are sedentary have a 1.2–2 fold increased risk of dying (Paffenbarger et al, 1994), with levels of cardiovascular fitness strongly associated with overall mortality (Berlin and Colditz, 1990). Physical activity provides a protective effect in later life, though taking up physical activity at any time can have an immediate effect on long-term morbidity (Paffenbarger et al, 1994).

A variety of studies have also shown that aerobic exercise improves self-esteem as well as having an antidepressant effect (Fox and Corbin, 1989; North et al, 1990; McDonald and Hodgdon, 1991; Scully et al, 1999; Frumkin, 2001; Pretty et al, 2005a). Exercise appears to affect an undetermined psycho-physiological mechanism, leading to improved fitness and/or weight loss, more autonomy and personal control, and a better sense of belonging and significance. However, there is much about the underlying mechanisms that is not known (Camacho et al, 1991; Farmer et al, 1998). It appears that if the amount of activity decreases in active individuals, then the risk of depression increases (North et al, 1990; McDonald and Hodgdon, 1991; Dishman, 1995). Paffenbarger et al (1994) found that men who engaged in three hours or more of sporting activity had a 27 per cent reduction in the risk of developing depression at follow-up compared to those who did an hour or less. There was also some important evidence for a dose response. Those who expended 10.5MJ or more per week were 28 per cent less at risk of developing clinically recognizable depression than those expending less than a 4MJ wk^{-1}; those who expended 4–10MJ wk^{-1} had a 17 per cent risk reduction compared to those in the least active group.

Physical activity in the country

The importance of sedentarization as a factor in reducing physical activity has been documented elsewhere in Canada amongst Cree communities, where efforts to increase physical activity have centred on aerobic classes, walking and cycling, and swimming (Lavalée et al, 1994), even though 19 per cent of those questioned said they preferred traditional activities such as wood-cutting or snowshoeing. Medical professionals working with the Innu have also recommended organized physical activities, but there has been little take-up as a result of ongoing social problems in the villages and the foreign nature of such activities which separate exercise from purposeful physical activity.

By contrast, physical activity in the context of hunting is an integral part of a way of life. Innu almost unanimously speak of hunting as fulfilling and therapeutic, providing a stark contrast to the inactive and stressful life in the villages. Observing the changes brought about when Innu leave the villages and spend months in the country, Andrew and Sarsfield (1984, p429) remark, 'alcohol abuse suddenly stops. A combination of improved diet, a rigorous lifestyle and the stable emotional and social environment offered by a functioning Innu society, make for a startling contrast with life in the villages.' In his seminal study of northern Athapaskan people, Brody (1981, p253) describes similar transformations in which 'tense people relax; the uncertain and shy become more confident', and all members of the hunting camp find the physical activity satisfying.

The activity transition for the Innu has been more rapid and pronounced than it has been for people in industrialized countries. Their transition has been from a nomadic lifestyle centred on physically demanding hunting, gathering and fishing to a modern lifestyle with its associated motorized vehicles and inactive jobs. As late as the end of the 1960s, the entire Mushuau Innu population was using dog teams, walking in winter on snowshoes and transporting themselves across long distances in blizzards, often under sub-zero temperatures with no guarantees of a successful hunt.

The anthropologist Henriksen (1973, pp21–24) recounts Innu endurance and stamina that indicates just how much physical activity could be involved in Innu life. The camp in which he was staying in the 1960s was situated 100 miles inland from Davis Inlet. There a group of men decided to go to the trading post to purchase some provisions. They rose at one in the morning and set off on sleds, taking turns to ride and run beside the sled. Some of the men shot ptarmigan along the way. They travelled non-stop until noon, having only a 15-minute tea break, before travelling further until five o'clock when it became dark. They then had to find a suitable campsite near a creek. The tent frame and supports were then fashioned from surrounding trees and the canvas tent thrown over the frame. A floor was built by shovelling away snow and then tramping down the remaining snow. The dog's meat was boiled and the dogs tied up before the men were able to prepare their own food for the night. After eating, the men got up and tramped down a path in the snow to make their passage easier the next day. They returned to the camp at one o'clock in the morning, having been up for 24 hours, then rose after two hours sleep and finally arrived at Davis Inlet by the next afternoon. After spending a short night at Davis Inlet, the group set off back for their camp 100 miles distant, and returned in the same fashion as the outward journey. Even today, with snowmobiles and outboard motors, the Innu hunting life is highly physically demanding for all members of the camp, from the older *Tshenut* to the children.

Energy expenditure

There are no time and motion studies to illustrate the precise difference in physical activities in the country compared with life in the village. However, both written records and the testimony of Innu indicate a large difference in energy expenditure. Table 4.4 summarizes the hourly calorific output for a selection of activities typical to both country and village life. In the country, most days involve long periods of physical activity. First, Innu have to get to where they will camp. In the past, this would have been by walking, with loads carried or dragged on sledges. Today, most use snowmobiles in winter. From the camp, men engage in hunting and trapping, and fuelwood cutting and hauling. Often they will be away for the whole day. Women engage in gathering plants and boughs of spruce for tent floors, snaring rabbits, setting nets for fishing, and a wide range of camp activities, including preparing and cooking foods, collecting water, looking after infants, repairing cloths and tents, and taking care of meat and hides. Jean-Pierre Ashini, interviewed in 2004, told us that, 'we were always busy in the country. I didn't consider this

Table 4.4 *Energy expenditure in various country and village activities (for adult of 77kg, 170lb)*

Activity	*Energy expenditure (MJ hour^{-1})*
Sitting or lying (watching TV)	0.42
Writing	0.54
Cooking	0.88
Shopping	1.21
Walking in country	1.59
Walking at 6.4kph (4mph)	1.88
Running across country	3.16
Fishing	1.21
Canoeing	1.42
Snowmobiling	1.46
Snowshoeing	3.26
Woodcutting with axe	3.76
Hand sawing	2.36
Stacking firewood	1.71
Playing ice hockey	4.01

Note: Energy expenditure rises with body weight (e.g. a 47kg (104lb) person snowshoeing expends 2MJ hr^{-1}, whereas a 98kg (216lb) person expends 4.1MJ hr^{-1}.
Source: McArdle et al, 1996

hard work'. Only when there were heavy snow storms or days of continuous rainfall did activity diminish in Jean-Pierre's camps (see also, Ambler, 1996; Pratt, 2002).

Hunting days would typically begin at daybreak so that Innu could maximize the hours of daylight while hunting. This could mean 12–15 hours of walking a day, which during the spring and summer would require 19–25MJ of energy expenditure, and up to 38–48MJ in winter. Another typical day might involve 6 hours of cutting trees and hauling wood for fuel – with an expenditure of 17.5MJ. Innu today recognize what such activity does to them physically. Jean-Pierre Ashini says, 'I eat a lot in the country, but I burn it off. Even though I am eating fatty foods, I am still 20–30 lbs lighter than when I live in the village'.

Some Innu recall acts of extraordinary physical endurance and capacity. Jean-Pierre Ashini recalls carrying a whole caribou of some 160kg weight some 2.5km back to camp. Dominic Pokue, interviewed in 2003, remembers as a young man canoeing 65km in two days, and travelling 110km in five days to reach camp at Minaipi Lake. Sometimes travel to the camp could involve walking both day and night, often carrying or dragging heavy loads. When men were hunting, they could travel very long distances, often spending 1–2 days away from the camp until they were successful in the hunt. Mary May Rich (interviewed in 2003) says women were active all day until they went to bed – chopping wood, collecting boughs, preparing foods. She did not consider this hard work, but an integral part of life and her identity. She said, 'I miss life in the country. It hurts to be in the village now.'

It is clear that physical activity in the country involves energy expenditure in excess of the normal recognized maximum intake for adult women and men (8–10MJ day^{-1}). A typical day in the village might only involve expenditure of 0.8–2.1MJ on physical activity (not counting sitting, lying, etc.). By contrast, a typical day in the country might involve expenditure of 12.5–50MJ, depending on time of year and activities. Consumption of food calories would therefore rarely exceed energy expenditure. In the village, however, intake greatly exceeds expenditure. For those Innu without jobs, a typical day may involve no more physical activity than an hour of walking from house to house or to the local store. Some children with bicycles may be more active and new sports facilities in the villages now occupy the time of some Innu children. Despite this, without access to the country, the Innu have little or no regular physical activity to fill the vacuum created by lack of hunting, trapping and gathering. It is, therefore, inevitable that energy input from food, even around recommended maximum intakes, will exceed expenditure. As we have shown, the situation is considerably worsened by the adoption of modern diets dense in fats and calories.

Restoring Country-based Activities

This disconnection from the country has a profound effect on the Innu's identity and their sense of connection to places and to each other. Underlying the nutritional and physical activity transitions is a fundamental change from largely self-reliant nomadic lifestyles in close contact with the land to welfare-dependent settled existences in villages. The Innu are virtually unanimous in describing *nutshimit* (the country) as synonymous with health (Samson, 2003a, pp255–262). Despite the open admission of some hardships, the country is depicted as providing the physical, mental and spiritual sustenance needed to survive as well as the social solidarity needed to maintain the Innu as a distinct society. For example, in a vast amount of Innu testimony on the changes imposed upon them since sedentarization, *nutshimit* was mentioned repeatedly as a source of healing and revitalization, often making direct links between wild food, physical activity, collective autonomy, and physical and psychological strength (Innu Nation and Mushuau Innu Band Council, 1995). Reports from explorers, scientists and other non-native observers before sedentarization also depict the Innu as a healthy, vibrant and self-reliant people, living into advanced age (Turner, 1979 [1889], p106; Tanner, 1944, pp599, 663).

The idea that being in the country can bring mental health and esteem benefits should not come as a surprise, as it has been established by a variety of empirical studies on largely urban-based people in industrialized countries (Pretty, 2004). These include analyses of the effects of views from the window or in pictures (Moore, 1981; Ulrich, 1984; Tennessen and Cimprich, 1995; Kaplan, 2001; Kuo and Sullivan, 2001; Diette et al, 2003), of incidental exposure to nature (Cooper-Marcus and Barnes, 1999; Wells, 2000; Whitehouse et al, 2001; Wells and Evans, 2003), and of immersion in wild nature (Hartig et al, 1991, 2003; Fredrickson and Anderson, 1999; Williams and Harvey, 2001; Herzog et al, 2002). We must, therefore, assume that the same applies to the Innu. This is reinforced by a growing body of research in social psychology and epidemiology relating to other aboriginal communities in Canada. These studies indicate that a command of traditional knowledge, spirituality, and higher levels of cultural continuity are associated with less suicide, solvent abuse and self-destructive tendencies (Chandler and Lalonde, 1998; Dell et al, 2002). Researchers noting the close association between suicide and rapid social and cultural change in the far north have recommended both 'activities directed towards continuity of valued practices … continue to be developed' (Kral, 2003, p38) and a 'recovery of tradition' (Kirmayer et al, 2003, pS16).

Given the profound loss of autonomy and change in lifestyle brought about by sedentarization, it is doubtful that the Innu will revert to permanent nomadic hunting. But, with only very limited wage labour options and no viable educational training or economic plan for the Innu villages, it is clear that country-based activities could be vital for both economic and cultural survival of a sizeable number of Innu. Several policy options are available to increase access to the country and its food whilst not contributing to any further natural resource declines. These would not represent a 'backward' step for the Innu, but would rather seek to make the best use of available technologies and practices. Several of these options have been tested elsewhere, such as the outstation movement for Aborigine communities in Australia (Morice, 1976) and ecotourism in Saami areas of Scandinavia and among indigenous peoples in Siberia. For the Innu, these options are not necessarily new. Some have been discussed for decades, but no action has been taken. There is now even more urgency for action.

We suggest four key policy changes:

1 a regional food policy to promote country food sourcing and consumption;
2 following the recommendations of the Canadian Human Rights Commission (Backhouse and McCrae, 2002), a fully-funded outpost or hunter support programme to strengthen regular connections to the country;
3 an ecotourism programme to increase visitor travel to the country and expenditure for Innu goods and services;
4 a new school calendar policy to ensure that children can visit the country for a month or more in spring and autumn without increasing their likelihood of being held back a year for missing school time.

Establish a food policy for country food

Some countries, such as Greenland, have progressive policies to support hunting lifestyles and consumption of country foods (Marquardt and Caulfield, 1996). The Greenland Home Rule government has been promoting local country food markets since 1988, and hunters regularly sell via formal kiosks, informally to relatives and neighbours, directly to schools, hospitals and senior citizens' homes, and directly to government-controlled processing facilities. The aim of the policy is to support country food consumption as a substitute for expensive and less healthy imported foods. At the same time, such a policy helps to promote the economic viability of indigenous communities. Country foods are not permitted to be exported. An important factor which enables this in Greenland is that there is effective indigenous control over land and sea tenure systems (Marquardt and Caulfield, 1996, p116).

Experience closer to Innu country shows that as long as Innu were able to maintain collective control of certain lands and waters, as consistent with the United Nations Draft Declaration on the Rights of Indigenous Peoples, such a policy could be a possibility. In the Inuit and Cree regions of northern Quebec, a Hunter's Support programme has been in existence since 1982 when the Quebec provincial government legalized it. The programme operates by the province releasing funds to aboriginal organizations that pay Inuit and Cree hunters for the meat and fish they bring home. It also helps to subsidize the purchase of hunting equipment, transportation and a small fee for the hunters' time. After taking some of the food from the hunters, the aboriginal organizations then distribute food throughout the villages for free. The aim of the programme is to encourage the perpetuation of hunting and to offer alternatives to aboriginal hunting families that are excluded from, or do not wish to participate in, wage labour (Kishigami, 2000).

It is clear that a similar policy could assist in maintaining hunting, fishing and trapping activities as well as improve the diets of the Innu. If pursued, such a governmental investment could be perceived as a preventive health measure, avoiding healthcare costs and averting some of the suffering associated with sedentary village life. To date, the government of Newfoundland has not been as imaginative as its Quebec counterpart in implementing such a programme.

A further suggestion is a policy in Labrador to encourage local food sourcing by stores and institutions (e.g. hospitals, schools). While this policy may conflict with the religious antipathy many Innu feel to the buying and selling of animals, especially the caribou, it would be possible to source some fish and wildfowl. How to revise incentives for the private food stores is more difficult. Northern stores in Canada are smaller than their southern counterparts, with, according to one study, 457 items compared with 10–20,000, and 20–50 times less the floor space (Green and Green, 1987). Very few sell fresh meat, fish and country foods. If an accelerated programme of activities in the country were to be initiated, however, a reinvigorated communal system of food distribution could make some commercial transactions superfluous and reduce reliance on cash.

Reinstate the Outpost programme

Access to the country now requires money and technologies, especially for older Innu. With no settler communities and few industrial incursions except the Voisey's Bay mine, the Innu in Natuashish can access the immediate country relatively easily. However, further excursions to favoured hunting and fishing locations such as Kamestastin and Ashuapun require snowmobiles or airplanes. Because of settler and industrial activity in Central Labrador, the Innu living in Sheshatshiu are more heavily reliant on money and technology to reach preferred locations in the country. Unfortunately, the Outpost programme which funded Innu hunting encampments in the autumn and spring of each year has been discontinued. This is despite a recommendation from the Canadian Human Rights Commission in 1993 that this programme should be continued indefinitely as a crucial enabler of Innu cultural continuity (Backhouse and McCrae, 2002, p7).

In this regard, the government has yet to honour its own obligations towards the Innu. The follow-up report concluded that 'the Government has not implemented that aspect of the second recommendation in the 1993 Report that called on the Government of Canada to preserve "the unique aspects of existing arrangements such as the outposts program"' (Backhouse and McCrae, 2002, p3). An immediate reinstatement of funding for this important project (or one like it) is necessary if Innu health is to be restored and cultural continuity maintained. While no research has been done on the uptake that a reintroduced Outpost programme would have, there is ample anecdotal evidence that large numbers of the Innu population would avail themselves of the opportunities to experience healthier and more meaningful activities in the country and remove themselves from the many sources of suffering and pain in the villages. A Band Council commissioned study of *Tshiskutamashun*, an Innu experiential learning project in the country in 1999, found widespread support for its continued existence, with unanimous support among adults (Samson, 2000/01; Samson, 2003a, pp218–221).

Promote ecotourism

At present, the Innu are almost totally reliant on funds from the Canadian state for their village-based livelihoods. Ecotourism provides an opportunity to build a small Innu economy that would encourage more contact with the country, while also having little ecological impact on the landscape. Possible projects could include many of those now being formulated by the Tshikapisk Foundation, an organization of Innu hunting families dedicated to revitalizing Innu country life through specifically Innu educational projects and revenue-generating activities. The Foundation has secured funds for the construction of an Innu cultural centre at Kamestastin Lake. From Kamestastin and other locations, the unspoiled terrain of boreal forests, rivers and tundra affords numerous opportunities for fishing, caribou migration viewing, trekking, cross-country skiing and variants of cultural tourism in which clients would share in Innu country activities of fishing, hunting and gathering. Paying clients would also be involved in learning camp skills, Innu crafts and events would be organized so that we would hear about the history of the Innu, including Innu legends and cosmology. Ecotourism along these lines could provide valuable funding for the various Tshikapisk experiential learning projects by which Innu youth could undertake a rigorous curriculum of Innu learning and be exposed to country life for a prolonged period of time. Equally important is that ecotourism could provide employment for those Innu preferring a more country-based life, lessening their dependence on welfare and government funds (Tshikapisk Foundation, 2004).

Amend the school calendar

A relatively simple adjustment to the school calendar could be made to assist Innu families with balancing country activities and village obligations. At present, schoolchildren are in session during the most important hunting seasons, the autumn and spring, and are on vacation during the long summer months when the presence of blackflies and the migration patterns of the animals make hunting less desirable. The Innu themselves and outside researchers including Henriksen (1993, p6) for the Mushuau Innu of Davis Inlet and Samson (2000/01) on behalf of the Sheshatshiu Innu Band Council have made recommendations to the Labrador School Board to change the calendar, but no action has been taken by the authorities.

In Quebec where several school boards have been devolved to Innu control, modifications to the school calendar, enabling Innu children to participate in hunting activities for short periods during the autumn and spring have been made. Similarly, the Cree School Board serving ten Cree communities around the James Bay and northern Quebec areas is strongly committed to instruction in the Cree language and value system. School calendars primarily follow the dominant North American model of instruction from August to June, but make some allowance for country activities in May through the 'floating goose break'. Although the Labrador School Board which controls Innu schools in Sheshatshiu and Natuashish has included 'culture days' in its curriculum, these consist primarily of *Tshenut* providing instruction in Innu skills or storytelling in the school building, and therefore, out of the predominant context of the country in which these are most meaningful (Samson, 2003a, pp189–192).

In some other parts of Canada, similar arrangements have been made to incorporate native activities within schools. On the whole, however, very little has been done across North America to reconcile the conflict between the statutory schooling schedule and the seasonal rhythms of Native American cultural activities. This is because an agricultural society model has simply been imposed, reflecting the need for 'summer holidays', originally designed to allow children to help with the harvests, a need which is nonsensical in the far north. The model was also indirectly imposed as a means of eradicating indigenous practices, sensibilities and orientations to time, and inculcating a different time discipline necessary for wage labour (Pickering, 2004).

Concluding Comments

If the scale of health problems experienced by indigenous populations with longer standing experiences of assimilation and colonization is any indication, the future of the Innu looks bleak. According to a recent report by the US Commission on Civil Rights (2004), Native Americans in the US are 770 per cent more likely to die from alcoholism, 650 per cent more likely to die from tuberculosis and 420 per cent more likely to die from diabetes than the general population. If figures could be obtained for the Innu they are likely to approximate to the US rates for alcoholism and diabetes, though not for tuberculosis.

Part of the problem lies in the fact that while much money is invested in treatments for the medical, social and psychological pathologies that afflict the Innu, hardly any resources are devoted to prevention. Canadian authorities take the contemporary village as the baseline for social intervention, devoting funds almost exclusively to village-based solutions. This is lamentable for the Innu who continue to receive largely Western-based institutional treatments. This, we argue, deals only with the individual symptoms of the larger processes of cultural, spiritual and physical dispossession incurred by sedentarization. It is also costly to continue to treat what are clearly preventable conditions. The costs of the treatment of the social and health problems arising from new diets and sedentary lifestyles are likely to far exceed the costs of a restoration of country-based activities we suggest here.

But this will require a fundamental change in the way local, regional and national policy makers conceive of the problems that the Innu face. Canadian policy makers will have to be more imaginative in working with the Innu. They will have to embrace 'bottom-up' ideas such as the various programmes offered by the Tshikapisk Foundation. Of course, it is not helpful to look to the government for all the answers. The initiatives of many Innu to spend time in the country practising their way of life, eating wild foods and benefiting from the plentiful exercise of country life is vital to the success of any of the positive changes we are endorsing in this paper. These endeavours could be facilitated by a combination of some government subsidies through an Outpost or Hunter Support programme and the development of non-profit revenue generation through ecotourism and other activities consonant with Innu hunting life.

It is clear, too, that the changes suggested here also have some relevance for people elsewhere in industrialized countries who are suffering ill-health from inappropriate diets and sedentary lifestyles. Better connections to food and the land, supported by reformed agricultural, food and land policies, could do much to promote wider and long-lasting changes in behaviour (Pretty, 2002; Pretty et al, 2004). However, the trends seen through most food systems towards commodification and processing of foods, combined with the self-interest of manufacturers and retailers, will make these changes difficult to sustain unless individuals and communities are able to take the links between health, food and the natural environment seriously, and act to develop new projects to address them. Being in the country for the Innu has considerable resonance for people in other societies who too have become disconnected from nature, land and food, yet who have a greater political voice to do something about these disconnections.

Acknowledgements

We are especially grateful to the many Innu people that have helped and hosted us. We thank Joseph Mark, Sebastien Rich, Basile Penashue, Dominic Pokue, Daniel Ashini, Mary Adele and Louis Penashue, Mary May Rich, Anastasia Qupee, Jean-Pierre Ashini, George Rich, Armand McKenzie and Anthony Jenkinson. We are also grateful to Stephen Loring for his comments on Innu pre-contact history, Marlene Atleo for her reflections on school calendars, and to two anonymous reviewers for their helpful comments.

Language: A Resource for Nature

Luisa Maffi

The concept of biocultural diversity is becoming increasingly familiar in environmental conservation circles internationally, especially since finding its way into international instruments such as the Convention on Biological Diversity (CBD) after the 1992 Rio Summit (UN Conference on Environment and Development). Article 8(j) of the CBD is specifically concerned with indigenous peoples, traditional knowledge and related rights. It states that each Contracting Party must:

> Subject to its national legislation, respect, preserve and maintain knowledge, innovations and practices of indigenous and local communities embodying traditional lifestyles relevant for the conservation and sustainable use of biological diversity and promote their wider application with the approval and involvement of the holders of such knowledge, innovations and practices and encourage the equitable sharing of the benefits arising from the utilization of such knowledge, innovations and practices.

Indigenous organizations have been very active vis-à-vis the implementation of Article 8(j) at the meetings of the Conference of the Parties (COP) to the CBD. At the latest meeting (COP IV, 4–15 May 1998, Bratislava, Slovakia), they succeeded in passing a decision that calls for the creation of a continuous working group in charge of advising on the measures necessary to protect indigenous peoples' knowledge, innovations and practices. In spite of persisting concerns about being actually enabled to participate in the working group and affect its recommendations, indigenous organizations consider this decision a success on the road to full recognition of the importance of their environmental knowledge and practices for the conservation and sustainable use of biological diversity.

While the processes surrounding the CBD have been in the spotlight, it is perhaps less well known that the first international document to incorporate an integrated notion of biocultural diversity was the Declaration of Belém of the International Society of Ethnobiology, elaborated in 1988 at the First International Congress of Ethnobiology in Belém, Brazil. Aware of the simultaneous

extinction threats facing tropical and other fragile ecosystems on the one hand, and indigenous peoples on the other, ethnobiologists stressed indigenous peoples' stewardship over the world's biological resources and affirmed the existence of an 'inextricable link' between cultural and biological diversity on Earth.

Interestingly, at about the same time, linguists were beginning to voice widespread concern on the status of the world's languages and to warn of another impending extinction crisis, of a magnitude and pace comparable to, if not greater than, that affecting biodiversity: one that would dramatically reduce linguistic diversity through the disappearance of most of the numerically small languages spoken by indigenous and minority peoples. In linguists' calls to action vis-à-vis this crisis, a parallel was often drawn with the loss of biodiversity, as a way of suggesting comparable damage to humanity's heritage. However, in these initial pronouncements, no significant attempt was made to go beyond such parallels and ask whether there might be more than a metaphorical relationship between these phenomena. It is only recently that this question has been explicitly asked and the idea proposed that, along with cultural diversity, *linguistic* diversity should also be seen as inextricably linked to biodiversity.[1] The present article[2] seeks to contribute to the debate on these issues and linkages.

Linguistic Diversify and Biodiversity

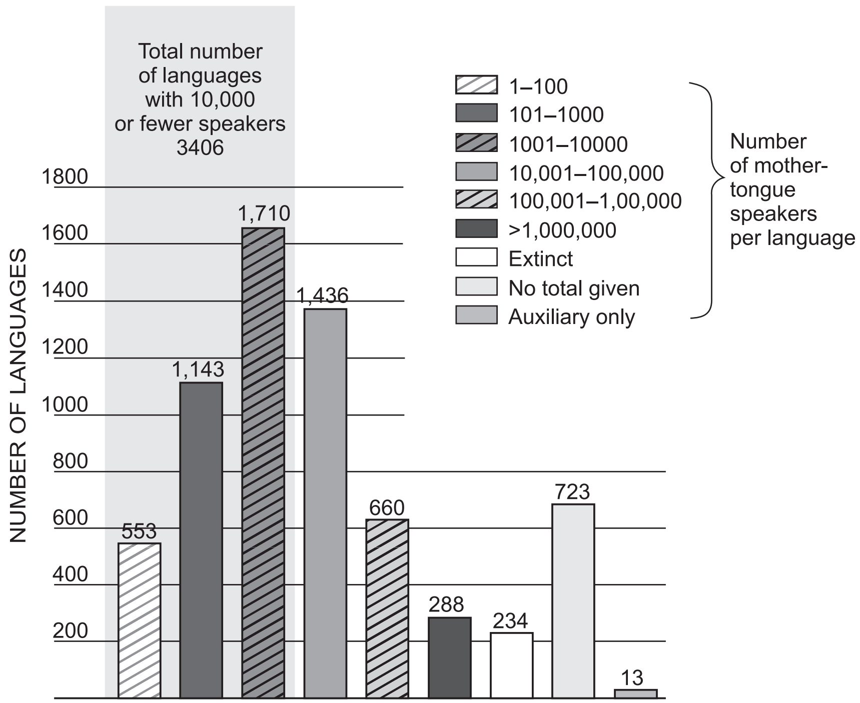
Defining and measuring linguistic diversity

In order to address this issue, let us begin by defining linguistic diversity. As with biodiversity, there are various definitions of linguistic diversity. Most commonly, however, the number of different languages spoken on Earth is used as a proxy for global linguistic diversity. There are an estimated 5000 to 7000 languages spoken today on the five continents, of which 32 per cent in Asia, 30 per cent in Africa, 19 per cent in the Pacific, 15 per cent in the Americas, and 3 per cent in Europe. Of these languages, about half are spoken by communities of 10,000 speakers or less; half of these, in turn, are spoken by communities of 1000 or fewer speakers (Figures 5.1–5.2). Overall, languages with up to 10,000 speakers total about 8 million people, less than 0.2 per cent of an estimated world population of 5.3 billion.[3]

On the other hand, of the remaining half of the world's languages, a small group of less than 300 (such as Chinese, English, Spanish, Arabic, Hindi and so forth) are spoken by communities of 1 million speakers or more, accounting for a total of over 5 billion speakers, or close to 95 per cent of the world's population (Figure 5.3). The top ten of these alone actually comprise almost half of this global population.

Indigenous and minority languages at risk

Taken together, these figures show that, while more than nine out of ten people in the world are native speakers of one, or other, of only about 300 languages, most



Source: From Harmon (1995)[3]

Figure 5.3 *Languages with the most mother-tongue speakers: proportion of world population*

of the world's linguistic diversity is carried by very small communities of indigenous and minority people. These are the languages that have been and continue to be under threat, due to the ever-growing assimilation pressures that promote incorporation of their speakers into 'mainstream' society and the collective abandonment of the native languages in favour of majority languages (a phenomenon known as 'language shift'). Virtually all languages with 1000 speakers or less are threatened in this sense, although even more widely spoken languages are fully susceptible to the same pressures. Many of these smaller languages are already at risk of disappearing due to a drastic reduction in the number of their speakers, with younger generations decreasingly or no longer learning their language of heritage. Many more have reached a stage of near extinction, with only a few elderly speakers left. Statistics on 'nearly extinct' languages range between 6 and 11 per cent of the currently spoken languages. In some projections, as many as 90 per cent of the world's languages may disappear during the course of the next century. These figures portray a threat to linguistic diversity that may be far greater and more imminent than the threat facing biodiversity.

It is a historical fact that languages, like biological species, have undergone extinction before. Informed guesses suggest that the peak of linguistic diversity on Earth may have occurred at the beginning of the Neolithic (10,000 years Before Present), at which time more than twice the current number of languages may have been spoken. Population movements and political and economic expansion have long contributed to reducing linguistic diversity everywhere in the world, even well before the era of colonization and empire building. As with biodiversity, however, what is unprecedented is an extinction crisis of the present magnitude and pace. It has been estimated that there may already be 15 per cent fewer languages now than 500 years ago, when the era of European colonization began.[4] Losses have been especially marked in the Americas and Australia. And the trend is now accelerating throughout the world, with Australia and the Americas (especially the US) still in the lead.

Causes of language loss

By and large, the main waves of colonial and imperial expansion in human history (both European and of other major civilizations) have come not only to the detriment of local peoples' sovereignty and control over their ancestral territories, resources and cultural traditions, but also to the detriment of their ancestral languages. Whenever assimilation into the dominant culture has been the goal (as it has been in most cases), this assimilation has been effected crucially by way of *linguistic* assimilation, through the imposition of the dominant language in schooling, the media, government affairs and most other public contexts – and, in parallel, through the denigration of the local languages (and the cultures they embody) as defective, primitive, unfit for the 'modern world', as well as through the severe restriction of their contexts of use and even the explicit prohibition of and punishment for their use. Awareness of the political implications of linguistic assimilation was perhaps never better expressed than by the 15th-century Spanish grammarian Antonio de Nebrija. In 1492, presenting Queen Isabella of Spain with his grammar of Spanish (the first grammar of any modern European language), Nebrija so explained its purposes in his introduction: 'Language has always been the consort of empire'.[5]

The 'curse of Babel' debunked

We may well feel sorry for the speakers of these smaller languages who have lost or are losing their ancestral tongues. But is it not the case that this linguistic assimilation is ultimately just an inevitable consequence of the in turn inevitable process of globalization the world is witnessing? Is this not, after all, a small price to pay for intercommunication and world stability? At long last, a widespread attitude has it, humanity will be freed of the burden laid upon it by the 'curse of Babel': the multiplicity of languages. With fewer different languages in use, this line of reasoning goes, it will be easier to communicate with people elsewhere in the world; once marginalized populations will be able to develop and prosper: ethnic conflict will decrease; national unity will no longer be threatened; and we will finally be moving toward the globalized cosmopolitan world that is the ultimate destiny of humanity.

However – whatever we may think about the inevitability of globalization and the ultimate destiny of humanity – none of these arguments is supportable. First, they are mostly expounded by speakers of languages that are comfortably not at risk of going extinct. Second, and very importantly, the learning of other languages does not have to occur at the cost of losing one's own language (in technical terms, it does not have to be subtractive); it can be additive, leading to a situation of stable multilingualism in one's mother tongue and one or more other languages. Again, it is rare for indigenous or minority groups to abandon their languages in favour of a majority one without direct or indirect pressures from governments and other outside forces. Faced with the challenges of modernity, indigenous and minority language speakers may or may not wish to preserve their own languages and cultural traditions, but should not have to find themselves systematically pressured into the latter choice. Indeed, one may seriously question whether choice under such pressure can be called choice at all.

Furthermore, marginalized ethnic groups who opt for or are forced into assimilation into a linguistic and cultural majority often do not succeed in overcoming their marginalization but end up among the dispossessed within 'mainstream' society. As for the issue of ethnic conflict and national security, specialized studies show that ethnic differences (whether identified with language, culture, religion, or any aspects of social organization) do not normally constitute the source of conflict, although they may be seized upon and attributed special meaning as a basis for mobilization when conflict arises. In particular, there is no evidence to suggest that the use of different languages by neighbouring populations may constitute *per se* a cause of conflict; nor, for that matter, does monolingualism within or between countries seem to be a guarantee for peace. When populations of speakers of different languages coexisting in adjacent or the same territory do come into conflict, the causes of such conflict reside more commonly in socioeconomic and political inequality and competition over land and resources, as well as in the denial (rather than the granting) of linguistic and cultural rights.[6]

The idea of Babel as a 'curse' is a widespread interpretation of this element of the Judaeo-Christian religious tradition, yet not necessarily a valid one. It is perhaps more accurate to see the divine intervention that brings about a multiplicity of languages as a way of curbing the arrogance and single-mindedness of monolingual empire builders. Other religious traditions suggest that a diversity of languages (and cultures) is a good thing. To cite just one example, according to the Acoma Pueblo Indians of New Mexico, the mother goddess latiku causes people to speak different languages so that it will not be as easy for them to quarrel.

Multilingualism and linguistic ecologies

Above all, these arguments completely ignore that – for most of human history, and even today in many parts of the world – high concentrations of different languages have coexisted side by side in the same areas. Over 800 different languages are still spoken in the island of New Guinea – the main hotspot of linguistic diversity. There and elsewhere, complex networks of multilingualism in several local languages and pidgins or lingua francas have been a commonplace way of dealing with cross-language communication in situations of contact. This extensive multilingualism has been a key factor in the maintenance of linguistic diversity historically, countering the increasing effects of linguistic assimilation.

Linguists are only beginning to realize that there may be structure to such linguistic diversity. The functional relationships that develop in space and time among linguistic communities that communicate across language barriers have been referred to as 'linguistic ecologies'. An ecological theory of language takes as its focus the diversity of languages *per se*, and investigates the functions of such diversity in the history of humanity. It seeks to identify the mechanisms that sustain a language ecology over time – which are, in fact, the very same mechanisms that will be required to build a genuine multilingual and multicultural society in today's global world. Furthermore, the study of traditional linguistic ecologies reveals that they encompass not only the linguistic and social environment, but also the physical environment, within a worldview in which physical reality and the description of that reality are not seen as separate phenomena, but instead as interrelated parts of a whole.[7]

Language and the Environment: the Inextricable Link

Overlap of linguistic and biological diversity

To understand how language and the environment may be seen as parts of the same whole, let us first consider some striking correlations between linguistic and biological diversity.[8] The majority of the smaller languages (which, as we have seen, account for most of the world's linguistic diversity) can be labelled as 'endemic', in that they are spoken exclusively within this or that country's borders. Comparing a list of countries by number of endemic languages with the IUCN list of 'megadiversity' countries, one finds that 10 out of the top 12 megadiversity countries (or 83 per cent) also figure among the top 25 countries for endemic languages (Table 5.1).

A global cross-mapping of endemic languages and higher vertebrate species brings out the remarkable overlap between linguistic and biological diversity throughout the world. Similar results can be obtained by cross-mapping endemic languages and flowering plant species.

Language, knowledge and human–environment coevolution

What may account for these correlations? Several geographical and environmental factors have been suggested that may comparably affect both biological and linguistic diversity, and especially endemism: (1) Extensive land masses with a variety of terrains, climates and ecosystems (e.g. Brazil, China, India, Mexico, US); (2) Island territories, especially with internal geophysical barriers (such as Australia,

Table 5.1 *Megadiversity countries: concurrence with endemic languages*

Concurrence: 10 of 12 (83%)

Countries in top 25 for endemic languages in bold*. Country listed alphabetically (endemic language rank in parentheses).

Source: *Modified from Harmon (in press). 'Megadiversity countries' have been identified as those likely to contain a large percentage of global species richness. The 12 listed were identified on the basis of species lists for vertebrates, swallowtail butterflies and higher plants

Indonesia, New Guinea, the Philippines); (3) Tropical climates, fostering higher numbers and densities of species (e.g. Cameroon, Democratic Republic of the Congo). All these factors are thought to increase linguistic diversity by increasing mutual isolation between human populations and thus favouring linguistic diversification.

In addition, an ecological phenomenon has also been proposed as possibly accounting for biodiversity-linguistic diversity correlations: a process of coevolution of small-scale human groups with their local ecosystems, in which over time humans interacted closely with the environment, modifying it as they adapted to it, and acquiring intimate knowledge of it. This knowledge was encoded and transmitted through the local languages, which thus became in turn moulded by and specifically adapted to their socio-ecological environments. As one linguist puts it: 'Life in a particular human environment is dependent on people's ability to talk about it.'[9]

This may sound like a truism worthy of little note, but it is not so. That remark embodies one of the most basic functions that language performs for humans, and in its deceptive simplicity reveals where the 'inextricable link' between language and the environment is to be found. At the local level, linguistic and cultural distinctiveness has often developed even among human groups defined as belonging to the same cultural area or whose languages are considered to be historically related, and who live within the same bioregion. As local groups have adapted to life in specific ecological niches, they have developed specialized knowledge of them, and specialized ways of talking about them, to convey this vital knowledge and ways of acting upon it for individual and group survival. What has been said of Australian Aboriginal tribes could be said in hundreds of other cases of local peoples around the world: 'Coincidences of tribal boundaries to local ecology are not uncommon and imply that a given group of people may achieve stability by becoming the most efficient users of a given area and understanding its potentialities.'[10]

Linguistically anthropogenic landscapes

In this light, then, it becomes possible to suggest that landscapes are anthropogenic (human-made) not only in the sense that they are physically modified by human intervention – as ethnobiologists and ethnoecologists have shown contra the myth of pristine wildernesses – but also because they are symbolically brought into the sphere of human communication by language: by the words, expressions, stories, legends, songs that encode and convey human relationships with the environment and that inscribe the history of those relationships onto the land.

Traditional place-naming also both occurs in an ecological context and carries high cultural significance for indigenous peoples, 'as a framework for cultural transmission and moral instruction, as a symbolic link to their land, and as a ground for their identity'. Named landmarks convey and evoke knowledge on both the physical environment and daily human activities, historical events, social relations, ritual and moral conduct: 'wisdom sits in places'.[11] Landscapes are networks of such places of knowledge and wisdom and thus, in this sense also, anthropogenic.

Losing the Link

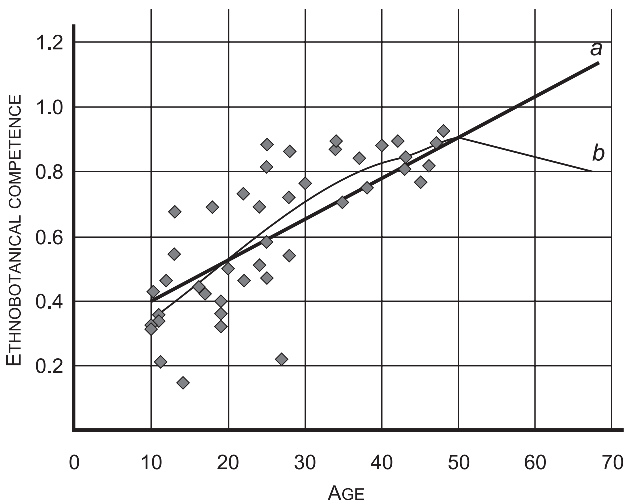
The extinction of experience

It is this inextricable link between language and the environment that is lost when external forces begin to undermine traditional cultures, pushing them into the 'mainstream'. Whether this process is propelled by dispossessing local peoples of their sovereignty over land and resources, trampling their cultural traditions, or promoting linguistic assimilation (generally, all three phenomena occur at once and are mutually reinforcing), the end result is the same. Local peoples lose control over, and contact with, their natural and cultural environments. As they are removed from their lands, or subsist in highly degraded ecosystems, and are absorbed into a market economy in which there normally is little room for traditional subsistence practices and resource use, local ecological knowledge and beliefs find the wisdom about human–environment relationships begin to lose their relevance to people's lives.

This phenomenon has been called the 'extinction of experience', the radical loss of direct contact and hands-on interaction with the surrounding environment.[12] In turn, local languages lose their crucial function of communicating and upholding such knowledge, beliefs and wisdom that are increasingly less significant and intelligible to younger generations. Furthermore, local knowledge does not 'translate' easily into the majority language to which minority language speakers switch; and along with the dominant language usually comes a dominant cultural framework that begins to take over and displace the traditional one. Because in most cases indigenous knowledge is only carried by oral tradition, when shift toward 'modernization' and dominant languages occurs and oral tradition in the native languages is not kept up, local knowledge is lost. Due to its place-specific and subsistence-related nature, local ecological knowledge is at an especially high risk of disappearing.

Knowledge loss

The patterns and factors of erosion of languages and linguistically encoded environmental knowledge are beginning to be systematically identified and quantified. For example, among the Piaroa Indians of Venezuela, the persistence of ethnobotanical knowledge has been found to negatively correlate with age, bilingualism and schooling (Figures 5.4–5.7).[13] Younger, more acculturated Piaroa show dramatically lower levels of competence than their older, less acculturated counterparts in identifying local plants by their Piaroa names and the cultural uses of those same plant species.



The regression lines drawn represent: (a) a linear or binomal model ($r^2 = 0.539$; $y = 0.2739 + 0.0126x$); and (b) a curvilinear or polynomial model ($r^2 = 0.625$; $y = 8.3118 + 0.4465x - 3.359\sqrt{x} - 15.7723x^2 - 0.0023x^3$).

Figure 5.7 *Regression of formal education and ethnobotanical competence among the Piaroa of Venezuela*

Often, the loss of traditional languages and cultures may be hastened by environmental degradation – such as logging, mining, agribusiness, cattle-raising and so forth – by creating a negative feedback loop. In the Yoeme pueblo of the Yaqui people of the Sonoran Desert in Arizona, the performance of Yoeme ritual is hampered by the disappearance from the local environment of many plant species that were traditionally employed in religious ceremonies. Ritual is one of the main contexts for the teaching of the Yoeme Truth, and in particular of the intimate spiritual and physical connection with and respect for nature. 'Yaquis have always believed that a close communication exists among *all* the inhabitants of the Sonoran desert world in which they live: plants, animals, birds, fishes, even rocks and springs. All of these come together as a part of one living community which Yaquis call the *huya ania*, the wilderness world … Yaquis regard song [as a part of ritual] as a special language of this community, a kind of "lingua franca of the intelligent universe".' The Yoeme elders' inability to correctly perform ritual due to environmental degradation thus contributes to precipitating language and knowledge loss, and creates a vicious circle that in turn affects the local ecosystem.[13]

Preserving and Restoring Language, Culture, and Land

Community efforts

The Yoeme example clearly shows how, for local peoples, the struggle for maintaining or restoring the integrity of their cultures, languages and environments configures itself as one interrelated goal. This holistic approach is increasingly evident in the grassroots efforts that are being made around the world. As an example, Native Californians are engaging in integrated biocultural conservation efforts. The linguistic and cultural revival activities in which they are involved go hand in hand with advocacy for environmental restoration on their lands and the renewed use of native plants for traditional handicrafts, such as basket-weaving, and for other purposes.

On the other hand, if acculturation has such measurably negative effects on traditional knowledge and languages, as in the case of the Piaroa, should local peoples reject the framework of modernity altogether, including the Western schooling that brings about dominant languages and cultural patterns – or, for that matter, the biomedical care that undermines the prestige of traditional medicine, and other similar cultural change? Some indigenous groups, such as certain Amazonian tribes, have made this choice, taking refuge deeper into the forest. Others have chosen to integrate aspects of the two worlds, for instance by combining formal schooling with curricula based on their own cultural traditions and formulated in their native languages. The Hawaiians and Maori have been at the forefront of the latter kind of approach. In still other cases, educational efforts have been aimed at marking the distinction between formal Western-type learning and traditional informal learning. In Australia, several Aboriginal groups use an approach whereby they separate 'white knowledge' (literacy, numeracy, etc.), taught by monolingual English-speakers, with White-Australian content and structure, from their own Aboriginal knowledge. Their own knowledge is 'lived' rather than taught in schools.[14]

The need for choices

Whatever choices local peoples may make – and as we have seen, they make a variety of them – what matters is that there *be* choices. As in the case of language learning (acquisition of a majority language does not have to be subtractive; it can and should be additive), it does not have to be a matter of either–or between different cultural frameworks (as it is far too often purported to be by dominant cultures). Local peoples must simply remain free to consciously choose if and how much of either framework – the traditional and the exogenous – they may wish to maintain or adopt. Some groups, as in the Amazonian case, may indeed choose isolation. But others, perhaps most, will probably choose some form of integration between, or parallel adoption of, frameworks. And in so doing, after all, they will not be doing anything different – if done in freedom and not under pressure –

from what humans throughout history have done in situations of contact: mixing and matching, which has contributed to so much of the cultural and linguistic diversity that we know today.

Language as a Resource

Linguistic diversity and the human potential

So far, questions about the consequences of loss of linguistic and cultural diversity have been raised mostly in terms of ethics and social justice, and of maintaining the human heritage from the past – and rightly so. However, when we consider the interrelationships between linguistic, cultural and biological diversity, we may begin to ask these questions also as questions about the future – as related to the continued viability of humanity on Earth. We may ask whether linguistic and cultural diversity and diversification may not share substantive characteristics with biological diversity and diversification, characteristics that are ultimately those of all life on Earth.

The relevant issues relate to the adaptive nature of variation in humans (as well as other species), and to the role of language and culture as providers of diversity in humans. Human culture is a powerful adaptation tool, and language at one and the same time enables and conveys much cultural behaviour. While not all knowledge, beliefs and values may be linguistically encoded, language represents the main instrument for humans to elaborate, maintain, develop and transmit such ideas. 'Linguistic diversity … is at least the correlate of (though not the cause of) diversity of adaptational ideas.' Therefore, it is possible to suggest that 'any reduction of language diversity diminishes the adaptational strength of our species because it lowers the pool of knowledge from which we can draw'.[15]

It is true that diversity characterizes languages (and cultures) not just with respect to one another, but also internally, with patterns of variation by geographical location, age grade, gender, social status and a host of other variables. This internal variation combines with the variation ensuing from historical contact among human populations propelling language and culture change and all manner of innovation. However, as more and more languages and cultural traditions are overwhelmed by more dominant ones and increasing homogenization ensues, one of the two main motors of change and innovation – the observation of linguistic and cultural difference – breaks down, or is seriously damaged. The end result is a global loss of diversity.

Avoiding 'cultural blind spots'

From this perspective, issues of linguistic and cultural diversity preservation may then be formulated in the same terms that have been proposed for biodiversity conservation: as a matter of 'keeping options alive' and of presenting 'monocultures of the mind'.[16] It has been argued that convergence toward majority cultural models increases the likelihood that more and more people will encounter the same 'cultural blind spots' – undetected instances in which the prevailing cultural model fails to provide adequate solutions to societal problems. Instead, '[i]t is by pooling the resources of many understandings that more reliable knowledge can arise'; and 'access to these perspectives is best gained through a diversity of languages'. Or simply stated: 'Ecology shows that a variety of forms is a prerequisite for biological survival. Monocultures are vulnerable and easily destroyed. Plurality in human ecology functions in the same way.'[17]

Supporting Linguistic, Cultural and Biological Diversity: the Role of Scientists

Benefit for the many or for the few?

Pronouncements on the importance of diversity often conclude on some universalistic note. Yet it is time to go beyond these general (and generic) statements, true as they may be. That we need diversity – cultural, linguistic, biological – for the benefit of humanity is undoubtedly true. But far too often, as local peoples are the first to know, the hailed 'benefit for humanity' has actually meant the benefit (and specifically the economic benefit) of a very small, privileged subset of said humanity, one that does not include that vast majority of humans in which most of this diversity resides. Ethnoscientists have realized to their dismay that they may have been even too successful in affirming the validity of traditional ethnobiological and ethnomedical knowledge – thus unwittingly attracting droves of unscrupulous bioprospectors ('biopirates') to the lands of the indigenous peoples whose knowledge they have painstakingly documented. Supporters of cultural diversity baulk at the thought that someone may now be earning large sums of money selling multicultural T-shirts in the places where cultural diversity least abounds. And if we are good enough at explicating and advocating for the role of language in the diversity equation, the time may not be far away when someone will begin to devise ways to make a business out of linguistic diversity – and not to the advantage of those who hold most of it.

Terralingua

As we work for the maintenance of cultural, linguistic and biological diversity, we must be constantly aware of these risks. And this is why research, applied work, and advocacy must go hand in hand today. This is not to say that basic research is no longer needed, but it is to say that it can no longer proceed in a vacuum, and that scientists need to educate themselves and others as to the nature and implications of what they do. It also means that scientists must become much better at listening to what indigenous and other local peoples around the world have to say about what they want and need, and be more prepared to ask if and how they can be of service.

With these thoughts in mind, in 1996, an international and multicultural group of scholars and professionals created the non-governmental organization Terralingua: Partnerships for Linguistic and Biological Diversity, which is devoted to a mixture of research, information, applied work and advocacy concerning the world's linguistic diversity and its relationships with biodiversity (Box 5.1).

Among the basic principles guiding Terralingua's work are:

- that the diversity of languages and their variant forms is a vital part of the world's cultural diversity;
- that biological diversity and cultural diversity (of which linguistic diversity is a major component) are not only related, but often inseparable, perhaps causally connected through coevolution;
- that, like biological diversity, linguistic diversity (represented mostly by indigenous languages) is facing rapidly increasing threats that are causing a drastic loss of both languages and the knowledge of which they are carriers, including knowledge on the environment and sustainable resource use;
- that the continued loss of linguistic, cultural and biological diversity will have dangerous consequences for humans and the Earth; and
- that, therefore, the fate of the lands, languages and cultures of indigenous peoples is decisive for the maintenance of biodiversity and linguistic and cultural diversity.[18]

Acknowledging the link

Over the past two years, Terralingua has been striving to promote this perspective both locally and globally in support of indigenous as well as minority communities' struggle to holistically preserve and protect their linguistic, cultural and natural environments through self-determination (or local determination in the case of local communities). It is apparent that these concerted efforts are beginning to make a difference, and that recognition of the inextricable link between linguistic and biological diversity is beginning to emerge internationally. The International Society of Ethnobiology has enshrined this perspective in its Draft Code of Ethics,[19] which states that: 'Culture and language are intrinsically connected to land and territory, and cultural and linguistic diversity are inextricably linked to biological diversity', and upholds the right to preserve and protect local languages as a part of the principle of self-determination. International bodies such as UNESCO, UNEP and the UN Centre for Human Rights are turning their attention to issues of indigenous languages within the framework of biocultural diversity preservation and the protection of the rights of indigenous peoples. It is likely that in the near future the notion of linguistic diversity will become as familiar as that of cultural

Box 5.1 *Terralingua … at a glance*

'Terralingua: Partnerships for Linguistic and Biological Diversity' is an international non-profit organization dedicated to:

- Supporting the perpetuation and continued development of the world's linguistic diversity, and
- Exploring the connections between linguistic, cultural and biological diversity.

Statement of purpose

A. Terralingua recognizes:

1. That the diversity of languages and their variant forms is a vital part of the world's cultural diversity;
2. That cultural diversity and biological diversity are not only related, but often inseparable; and
3. That, like biological species, many languages and their variant forms around the world are now faced with an extinction crisis whose magnitude may well prove very large.

B. Terralingua declares:

4. That every language, along with its variant forms, is inherently valuable and therefore worthy of being preserved and perpetuated, regardless of its political, demographic or linguistic status;
5. That deciding which language to use, and for what purposes, is a basic human right inhering to members of the community of speakers now using the language or whose ancestors traditionally used it; and
6. That such usage decisions should be freely made in an atmosphere of tolerance and reciprocal respect for cultural distinctiveness – a condition that is a prerequisite for increased mutual understanding among the world's peoples and a recognition of our common humanity.

C. Therefore, Terralingua sets forth the following goals:

7. To help preserve and perpetuate the world's linguistic diversity in all its variant forms (languages, dialects, pidgins, creoles, sign languages, languages used in rituals, etc.) through research, programmes of public education, advocacy and community support.
8. To learn about languages and the knowledge they embody from the communities of speakers themselves, to encourage partnerships between community-based language/cultural groups and scientific/professional organizations who are interested in preserving cultural and biological diversity, and to support the right of communities of speakers to language self-determination.
9. To illuminate the connections between cultural and biological diversity by establishing working relationships with scientific/professional organizations and individuals who are interested in preserving cultural diversity (such as linguists, educators, anthropologists, ethnologists, cultural workers, native advocates, cultural geographers, sociologists, and so on) and those who are interested in preserving biological diversity (such as biologists, botanists, ecologists, zoologists, physical geographers, ethnobiologists, ethnoecologists, conservationists, environmental advocates, natural resource managers and so on), thus promoting the joint preservation and perpetuation of cultural and biological diversity.
10. To work with all appropriate entities in both the public and private sectors, and at all levels from the local to the international, to accomplish the foregoing.

diversity in the debates surrounding international instruments concerned with biodiversity, such as the CBD.

As this process unfolds, we are coming full circle to a holistic view of language, culture and land that may have once characterized localized human communities throughout the world, and that indigenous peoples today are holding up for the rest of humanity to see.

Notes

1 On language endangerment, see especially: Krauss, M. 1992. The world's languages in crisis. *Language* 68(1): 4–10. An integrated perspective on linguistic, cultural and biological diversity was developed in particular at the international interdisciplinary working conference 'Endangered Languages, Endangered Knowledge, Endangered Environments' (Berkeley, California, 25–27 October 1996). Part II

Early Agriculture

6

Our Vanishing Genetic Resources

Jack R. Harlan

All of the major food and fibre crops of the world are of ancient origin. The main sources of human nutrition today are contributed by such plants as wheat, rice, corn, sorghum, barley, potatoes, cassava, taro, yams, sweet potatoes and grain legumes such as beans, soybeans, peanuts, peas, chickpeas and so on. All of these plants were domesticated by Stone Age men some thousands of years ago and had become staples of the agricultural peoples of the world long before recorded history. We are not able to trace with certainty the genetic pathways that led to domestication, but we do know that these crops evolved for a long time under the guidance of man living in a subsistence agricultural economy. In the process of evolution, the domesticated forms often became strikingly different from their wild progenitors and generated enormous reserves of genetic variability.

Darwin opened his book *On the Origin of Species* with a discussion of variability of plants and animals under domestication. Genetic variability is the raw stuff of evolution, and he was struck by the range of morphological variation found in domesticated forms in contrast to their wild relatives. We are all familiar with the enormous differences among such breeds of dogs as Pekingese, dachshund, beagle, bulldog, Afghan and Great Dane and how far removed they are in appearance from either wolves or any other wild species that could have been progenitor to domestic dogs. Similar ranges of diversity are seen in chickens, pigeons, cats, cattle, horses and so on. Domestic plants exhibit the same phenomenon, especially among species that have been cultivated for a very long time and that have wide distributions. Genetic diversity is essential for evolution in nature and is, obviously, equally necessary for improvement by plant breeding.

Crop evolution through the millennia was shaped by complex interactions involving natural and artificial selection pressures and the alternate isolation of stocks followed by migrations and seed exchanges that brought the stocks into new environments and that permitted new hybridizations and recombinations of characteristics. Subsistence farmers of what we often call 'primitive' agricultural societies have an intimate knowledge of their crops and a keen eye for variation.

From Harlan J R. 1975. Our vanishing genetic resources. *Science* 188: 618–621. Reprinted with permission from AAAS.

Artificial selection is often very intense, for the only forms to survive are those that man chooses to plant. The end products that emerged in primitive agricultural systems were variable, integrated, adapted populations called land races.

While land race populations are variable, diversity is far from random. They consist of mixtures of genotypes or genetic lines, all of which are reasonably well adapted to the region in which they evolved but which differ in detail as to specific adaptations to particular conditions within the environment. They differ in reaction to diseases and pests, some lines being resistant or tolerant to certain races of pathogens and some to other races. This is a fairly effective defence against serious epiphytotics. Some components of the population are susceptible to prevalent pathogenic races, but not all, and no particular race of pathogen is likely to build up to epiphytotic proportions because there are always resistant plants in the population. Land races tend to be rather low yielding but dependable. They are adapted to the rather crude land preparation seeding, weeding and harvesting procedures of traditional agriculture. They are also adapted to low soil fertility; they are not very demanding, partly because they do not produce very much.

Land races have a certain genetic integrity. They are recognizable morphologically; farmers have names for them and different land races are understood to differ in adaptation to soil type, time of seeding, date of maturity, height, nutritive value, use and other properties. Most important, they are genetically diverse. Such balanced populations – variable, in equilibrium with both environment and pathogens, and genetically dynamic – are our heritage from past generations of cultivators. They are the result of millennia of natural and artificial selections and are the basic resources upon which future plant breeding must depend.

In addition to variable land race populations, traditional agriculture generated enormous diversity in identifiable geographic regions called 'centres of diversity' or 'gene centres'. Such centres are (or were) found on every continent, except Australia where the native people did not cultivate plants. Wherever they are located they are always characterized by (i) very ancient agriculture, (ii) great ecological diversity (usually mountainous regions), and (iii) great human diversity in the sense of numerous culturally distinct tribes with complex interacting histories. Centres of diversity were first recognized and described by the great Russian agronomist and geneticist N. I. Vavilov in the 1920s and 1930s.[1]

H. V. Harlan and M. L. Martini, concerned with genetic resources of barley, put it this way as early as 1936:

> In the great laboratory of Asia, Europe and Africa, unguided barley breeding has been going on for thousands of years. Types without number have arisen over an enormous area. The better ones have survived. Many of the surviving types are old. Spikes from Egyptian ruins can often be matched with ones still growing in the basins along the Nile. The Egypt of the Pyramids, however, is probably recent in the history of barley. In the hinterlands of Asia there were probably barley fields when man was young. The progenies of these fields with all their surviving variations constitute the world's priceless reservoir of germ plasm. It has waited through long centuries. Unfortunately, from

> the breeder's standpoint, it is now being imperiled. When new barleys replace those grown by the farmers of Ethiopia or Tibet, the world will have lost something irreplaceable.[2]

That is the way it was before World War II. Genetic erosion was already well advanced in much of Europe, the US, Canada, Japan, Australia and New Zealand, where active plant-breeding programmes had been under way for some decades. But, the ancient reservoirs of germ plasm were still there in the more remote parts of the world and seemed to most people as inexhaustible as oil in Arabia. We could afford to squander our genetic resources because we never had much of our own, and we could always send collectors to such places as Turkey, Afghanistan, Ethiopia, India, South-east Asia, China, Mexico, Colombia and Peru and assemble all the diversity we could use. No one paid much attention to the prophetic warning of Harlan and Martini.

International Programmes for Genetic Resource Conservation

After World War II, the picture began to change. Modern plant-breeding programmes were established in many of the developing nations and often right in the midst of genetically rich centres of diversity. Some of the programmes were successful, and new, uniform, high-yielding, modern varieties began to replace the old land races that had evolved over the millennia. The speed with which enormous crop diversity can be essentially wiped out is astonishing, and the slowness with which people have reacted to salvage of threatened genetic resources is dismaying.[3]

Cries of alarm began to be sounded on the international scene about 15 years ago. A short chronology of events and actions associated with the Food and Agriculture Organization (FAO) of the United Nations is presented below.

1961 FAO convened a technical meeting on plant exploration and introduction. Among the recommendations was one to the effect that a panel of experts be appointed 'to assist and advise the Director of the Plant Production and Protection Division in this field'.

1962 A proposal for a Crop Research and Introduction Centre, Izmir (Turkey), was submitted to the UN Special Fund.

1963 The twelfth session of the FAO conference also recommended the establishment of a Panel of Experts on Plant Exploration and Introduction to advise FAO on these matters.

1964 The Crop Research and Introduction Centre, Izmir, became operative with UN Special Fund support. The Centre has collected, stored and distributed germ plasm and now, under support of the Swedish government, is serving as a regional centre for the Near East.

1965 The panel of experts was appointed.
1967 FAO and the International Biological Program (IBP) jointly sponsored a Technical Conference on Exploration, Utilization and Conservation of Plant Genetic Resources.[4]
1968 A Crop Ecology and Genetic Resources Unit was established in the Plant Production and Protection Division, FAO.
1971 The Consultative Group on International Agricultural Research (CGIAR) was established under joint sponsorship of the World Bank, FAO and UN Development Programme (UNDP). Members include governments, private foundations and regional development banks, and money is generated to support international agricultural research programmes and institutes.
1971 A Technical Advisory Committee (TAG) was established to assist the CGIAR.
1972 Under joint sponsorship of TAC, FAO and CGIAR a meeting was convened at Beltsville, Maryland, and a plan for a global network of Genetic Resources Centres was drawn up. Recommendations for location and funding were made and suggestions for international organization and coordination submitted to CGIAR through TAC.
1972 The UN Stockholm Conference on the Human Environment called for action on genetic resource conservation.
1973 A second FAO/IBP technical conference was convened in Rome.[5]
1973 The CGIAR established a subcommittee on genetic resources,
1973 The International Board for Plant Genetic Resources (IBPGR) was established with a secretariat in FAO and financial resources provided by CGIAR, as recommended at the Beltsville meeting.
1974 Portions of the global strategy devised at Beltsville began to be funded through bilateral agreements with donor governments; for example, Sweden agreed to support the Izmir Centre for a time, and the Federal Republic of Germany agreed to support genetic resources centres in Ethiopia and Costa Rica. Other similar agreements have been or are being arranged.

Within the FAO structure, rather parallel developments took place with respect to forest genetic resources. Reports of technical conferences and meetings of the panel of experts, *Plant Introduction Newletter* and *Forest Genetic Resources Information* are published by FAO.

It must be admitted that for all the organizational developments, and despite repeated and urgent pleas by the panel of experts, remarkably little collecting has been done to date. The Izmir Centre has been plagued with political, financial, administrative and personnel problems from the start. It has managed to assemble a modest collection of some 10,000 accessions, and the long-term storage facilities now installed are excellent. The conception of the Izmir Centre is sound, and it is to be hoped that it will eventually perform the function for which it was established. FAO has conducted a few collecting expeditions and has given support to more, but the urgency of the situation demands much more vigorous action than has been generated so far.

The next few years, however, should show an increase in plant exploration. Funds should be available from the consultative group to support adequate exploration programmes. For some regions it will probably be too late to salvage much.

It must also be admitted that much less would have been achieved without the dogged and determined insistence of Sir Otto Frankel of Australia.[4] Through the years he has refused to abandon hope that serious action could, one day, be launched through an international cooperative programme, and he has shaped most of the events described above.

Meanwhile, the international institutes, supported largely by CGIAR, have fared somewhat better. They each deal with one or a few crops and have usually understood that a part of the mission was to assemble and preserve germ plasm of the crops being developed. The world maize collection, for example, traces back to early international agricultural research sponsored by the Rockefeller Foundation in Mexico, Colombia and elsewhere. A rather systematic effort was made to collect the races of maize, country by country, throughout Latin America. A major portion of the collection is maintained by the Centro Internacional de Mejoramento de Maíz y Trigo (CIMMYT) in Mexico, the Andean collection by the Instituto Colombiano Agropecuario (ICA) in Colombia, and the eastern South American collection is maintained at Piracicaba, Brazil. The maize collection appears to be in reasonably good shape, although some additional exploration is desirable.

The world rice collection has been growing rapidly in recent years through activities of the International Rice Research Institute (IRRI) in the Philippines. It is certainly not complete, but it is far better than it was 3 to 4 years ago. The Centro Internacional de Agricultura Tropical (CIAT) in Colombia is assembling cassava and beans. The International Institute of Tropical Agriculture (IITA) in Nigeria has been collecting cowpeas, pigeon peas, yams and other tropical tuber crops, and tropical vegetable species. The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Hyderabad, India, has assumed responsibility for world collections of sorghum, millets, chickpeas and pigeon peas. The Centro Internacional de Papas (CIP) in Peru is starting to assemble potatoes for breeding work. All of these institutes are located in the tropics and should be able to maintain and rejuvenate collections of these crops much more efficiently than can be done in temperate countries.

National Programmes: US

The agriculture of the US is an imported agriculture. Even crops domesticated by the American Indians – such as corn, potatoes, peanuts, cotton, tomatoes and so on – originated in Latin America outside of the US, and were introduced, some by Indians and some by Europeans. Because of our dependence on exotic germ plasm, the national government has sponsored collections and introductions from the beginning. As early as 1819, the Secretary of the Treasury issued a circular requesting Americans serving as consuls to send useful plant materials back to the US. Formal plant exploration was conducted by the Office of the Patent Commissioner before 1862, when the US Department of Agriculture (USDA) was created. In 1898 a Section of Seed and Plant Introduction was established in the USDA; and ever since, through various name changes and reorganizations, some unit within the department has been charged with responsibility for germ plasm assembly and maintenance.[6]

A considerable impetus was given to the plant introduction programme by the Research and Marketing Act of 1946. Regional Plant Introduction Stations were established in the four administrative regions of the country. An Inter-Regional Potato Project was established in 1949 with a special station at Sturgeon Bay, Wisconsin, where exotic potato germ plasm could be grown and evaluated. A National Seed Storage Laboratory was built in Fort Collins, Colorado, and began operation in 1958. The primary objective of the laboratory is long-term seed storage, although research on the physiology of germination, dormancy and longevity of seeds is also conducted.

Nearly 400,000 accessions have been introduced since 1898, but there has been substantial attrition over the years. The importance of maintenance was not at first generally realized, and much material was lost for one reason or another. Nevertheless, the present holdings of the USDA are very considerable and extremely important. The small grains (wheat, barley, oats and rye) collection, for example, consists of more than 60,000 items, many of which could not possibly be replaced because they have disappeared from their original homelands. Substantial 'world collections' of the major crops and many of the minor ones are being maintained at the Regional Plant Introduction Stations or through cooperative arrangements with other state and federal stations.

It would be nice to think that all the genetic diversity we will ever need is safely stored away in gene banks for future use. Unfortunately this is hardly the case. Some of our collections are large even when the numerous duplicates are accounted for, but none is really complete, and sources of diversity are drying up all over the world. We are particularly deficient in the wild and weedy relatives of our more important crops, and some geographic regions have been very poorly sampled. While the USDA has sponsored plant introduction work from the beginning, it has never been able to obtain enough support to systematically sample the world's germ plasm. The National Seed Storage Laboratory has received step-child treatment with no increase in the operating budget for more than 15 years after establishment.

The southern corn leaf blight epidemic in 1970 aroused some activity in the area of crop vulnerability. A survey was commissioned by the National Academy of Sciences, resulting in a report on genetic vulnerability.[7] It was found, not surprisingly, that not only corn but also every major crop we grow has a very narrow genetic base. The entire soybean industry, for example, traces back to six introductions from the same part of China. The leaf blight epidemic of 1970 came about because most of the hybrids produced had a common cytoplasm which conferred susceptibility to a particular race of the pathogen. We are just as vulnerable in sorghum where a cytoplasmic sterile system is used to produce hybrids. A crop-by-crop analysis reveals an extremely risky dependence on narrow genetic bases.

More than this, the number of crops we grow has been declining steadily. More and more people are being fed on fewer and fewer crops and these are becoming increasingly uniform, genetically.

After a series of meetings in Washington, an ad hoc committee drew up recommendations and presented them to the Agricultural Research Policy Advisory Committee (ARPAC) of the Agricultural Research Service. Among the recommendations was the establishment of a Genetic Resources Board at the national level which would, among other things, devise a national plan and programme for systematic assembly, maintenance, evaluation and utilization of plant genetic resources. It is to be hoped that a more systematic, coordinated and effective programme of genetic resource management can be generated for the country and that adequate financial support can be found. Approval for the board was obtained in January 1975.

National Programmes: Other Countries

The USSR probably has holdings of about the same magnitude as ours. No doubt, there is a good deal of duplication, yet they have arrays of collections that we do not have and we have materials they do not have. It would undoubtedly be of great mutual benefit if we could exchange collections and hold a complete set of duplicates in two different parts of the world. It would be a disaster if something should happen to either collection. Duplicate storage would be much safer.

National collections can be vulnerable. There is a heroic tale about the siege of Leningrad during World War II. People were dying of cold and starvation, reduced to eating rats, cats, dogs, dried glue from furniture joints and wall paper, or anything else that might prolong life. All this time, truckloads of edible seeds were in storage at the All-Union Institute of Plant Industry. The seeds were too precious to be sacrificed even at the cost of human life, and the collections survived for future use. We may pray that such a threat will never occur again, but prayer may not be adequate to save priceless genetic resources.

The Vavilovian emphasis on plant genetic resources persisted despite the long twilight of genetics under the political influence of T. D. Lysenko and Vavilov's tragic death as a result.[8] The institute, which he directed for 20 years (1920–1940), was renamed the N. I. Vavilov All-Union Institute of Plant Industry (VIR) in 1968, just in time for the 75th anniversary of the organization in 1969.[9]

There may be some question as to how well the original collections of the Vavilovian era have been maintained with respect to genetic authenticity, but there is no doubt that Soviet scientists are more collection minded than plant scientists elsewhere. Genetic resource management has been emphasized since 1920 and has become an integral part of the national agricultural development programme. No doubt there are genes in Soviet collections that no longer exist anywhere else.

The Japanese, under the stimulus of H. Kihara, have also had strong genetic conservation programmes, especially with certain crops. Expeditions have been sent to several centres of diversity over the decades and a national seed storage facility has been established at Hiratsuka. The University of Kyoto and the National Institute of Genetics, Misima, have been especially active, although others have also participated.

Genetic resources centres with cold storage for long-term conservation have been established in a number of other countries. Some of the major ones include Brisbane, Australia; Prague, Czechoslovakia; Copenhagen, Denmark; Gatersleben, German Democratic Republic; Braunschweig-Volkenröde, German Federal Republic; New Delhi, India; Bari, Italy; Wageningen, Netherlands; and Warsaw, Poland. Others are being constructed or present facilities are being upgraded. Substantial holdings are being maintained in the UK, France, Sweden, Canada and elsewhere. The necessity for genetic conservation is gradually being accepted throughout the world, but the urgency of salvage collection operations has yet to be generally appreciated.

A recent visit by a Plant Studies Delegation to the People's Republic of China revealed a somewhat ambiguous situation. The following observations may be pertinent. (i) China is, indeed, very rich in genetic diversity for many crops; (ii) Chinese scientists are not collection minded, and little effort is being made to conserve land races as they are replaced by modern varieties; (iii) the trend, at the moment, is to produce many species and varieties of fruits and vegetables, which tends to maintain diversity; and (iv) there is a strong emphasis on local self-sufficiency with respect to seed production at both the people's commune and production brigade levels which may tend to maintain variability at the national level. Overall, the picture is discouraging with respect to major crops. Two rice collections are being maintained, one for *japonica* and one for *indica* rices, but the ancient kaoliangs are disappearing from the Chinese sorghum belt, and the traditional millets are hanging on primarily in marginal dryland zones.

Altogether, a good deal has been done to collect genetic resources, and tentative, if unsystematic, steps have been taken to conserve much of it on a long-term basis. In view of the obvious limitations of our collections and in face of the current genetic 'wipe out' of centres of diversity, it may be too little and too late. We continue to act as though we could always replenish our supplies of genetic diversity. Such is not the case. The time is approaching, and may not be far off, when essentially all the genetic resources of our major crops will be found either in the crops being grown in the field or in our gene banks. This will be a risky state of affairs and will demand a great deal more time and effort on genetic resource management than we have ever devoted to it in the past.

Oriental Despotism

K. Wittfogel

The characteristics of hydraulic economy are many, but three are paramount. Hydraulic agriculture involves a specific type of division of labour. It intensifies cultivation. And it necessitates cooperation on a large scale. The third characteristic has been described by a number of students of Oriental farming. The second has been frequently noted, but rarely analysed. The first has been given practically no attention. This neglect is particularly unfortunate, since the hydraulic patterns of organization and operation have decisively affected the managerial role of the hydraulic state.

Economists generally consider the division of labour and cooperation key prerequisites of modern industry, but they find them almost completely lacking in farming.[1] Their claim reflects the conditions of Western rainfall agriculture. For this type of agriculture it is indeed by and large correct.

However, the economists do not as a rule so limit themselves. Speaking of agriculture without any geographical or institutional qualification, they give the impression that their thesis, being universally valid, applies to hydraulic as well as to hydroagriculture and rainfall farming. Comparative examination of the facts quickly discloses the fallacy of this contention.

A. Division of Labour in Hydraulic Agriculture

1. Preparatory and protective operations separated from farming proper

What is true for modern industry – that production proper depends on a variety of preparatory and protective operations[2] – has been true for hydraulic agriculture since its beginnings. The peculiarity of the preparatory and protective hydraulic operations is an essential aspect of the peculiarity of hydraulic agriculture.

Reprinted from Wittfogel K. 1957. *Oriental Despotism*. Yale University Press, New Haven, Chapter 2, pp22–48.

a. Large-scale preparatory operations (Purpose: irrigation)

The combined agricultural activities of an irrigation farmer are comparable to the combined agricultural activities of a rainfall farmer. But the operations of the former include types of labour (on-the-spot ditching, damming and watering) that are absent in the operations of the latter. The magnitude of this special type of labour can be judged from the fact that in a Chinese village a peasant may spend from 20 to over 50 per cent of his work time irrigating, and that in many Indian villages irrigation is the most time-consuming single item in the farmer's budget.[3]

Hydroagriculture (small-scale irrigation farming) involves a high intensity of cultivation on irrigated fields – and often also on non-irrigated fields.[4] But it does not involve a division of labour on a communal, territorial or national level. Such a work pattern occurs only when large quantities of water have to be manipulated. Wherever, in pre-industrial civilizations, man gathered, stored and conducted water on a large scale, we find the conspicuous division between preparatory (feeding) and ultimate labour characteristic of all hydraulic agriculture.

b. Large-scale protective operations (Purpose: flood control)

But the fight against the disastrous consequences of too little water may involve a fight against the disastrous consequences of too much water. The potentially most rewarding areas of hydraulic farming are arid and semi-arid plains and humid regions suitable for aquatic crops, such as rice, that are sufficiently low-lying to permit watering from nearby rivers. These rivers usually have their sources in remote mountains, and they rise substantially as the summer sun melts part of the snow accumulated there.

Upstream developments of this kind cause annual inundations in Egypt, Mesopotamia, Turkestan, India, China and in the Andean and Mexican zones of America. In semi-arid areas on-the-spot rains create additional dangers when they are overconcentrated (convectional) or irregular. This condition prevails in North China, northern Mesopotamia (Assyria) and the Mexican lake region. Thus a hydraulic community that resorts to preparatory labour to safeguard the productive use of water may also have to resort to protective labour to safeguard its crops from periodic and excessive inundations.

When, in protohistorical times, the Chinese began to cultivate the great plains of North China, they quickly recognized that the centres of greatest potential fertility were also the centres of greatest potential destruction. To quote John Lossing Buck: 'Geologically speaking, man has settled these plains thousands of years before they were ready for occupation.'[5] The Chinese built huge embankments which, although unable to remove entirely the risk inhering in the ambivalent situation, matched and even surpassed in magnitude the area's preparatory (feeding) works.[6]

In India enormous problems of flood control are posed by the Indus River[7] and, in a particularly one-sided way, by the Ganges and Brahmaputra Rivers, which in Bengal create optimal conditions for the cultivation of rice and maximal dangers from floods. By 1900 Bengal boasted 97 miles of larger irrigation canals and 1298 miles of embankments.[8]

In ancient Mesopotamia even watchful rulers could not completely prevent the inundations from damaging the densely settled plains.[9] In Turkestan excessive floods periodically threatened the Zarafshan River Valley.[10] In Upper Egypt the Nile, in very high flood, rises 1 metre above the level of the settled countryside, in Middle Egypt 2 metres, and in the Delta area up to 3.5 metres.[11] The inhabitants of the lake area of Mexico could benefit from its fertility only if they accepted the periodic overflow of its short, irregular, narrow streams,[12] which they sought to control through a variety of protective works. Thus in virtually all major hydraulic civilizations, preparatory (feeding) works for the purpose of irrigation are supplemented by and interlocked with protective works for the purpose of flood control.

2. Cooperation

A study of the hydraulic patterns of China (especially North China), India, Turkestan, Mesopotamia (especially Assyria), Egypt or Meso-America (especially the Mexican lake region) must therefore consider both forms of agrohydraulic activities. Only by proceeding in such a way can we hope to determine realistically the dimension and character of their organizational key device: cooperation.

a. Dimension

When a hydraulic society covers only a single locality, all adult males may be assigned to one or a few communal work teams. Varying needs and circumstances modify the size of the mobilized labour force. In hydraulic countries having several independent sources of water supply, the task of controlling the moisture is performed by a number of separated work teams.

Among the Hill Suk of East Africa, 'every male must assist in making the ditches'.[13] In almost all Pueblos 'irrigation or cleaning a spring is work for all'.[14] Among the Chagga, the maintenance of a relatively elaborate irrigation system is assured by 'the participation of the entire people'.[15] In Bali the peasants are obliged to render labour service for the hydraulic regional unit, the *subak*, to which they belong.[16] The masters of the Sumerian temple economy expected every adult male within their jurisdiction 'to participate in the digging and cleaning of the canals'.[17] Most inscriptions of Pharaonic Egypt take this work pattern for granted. Only occasionally does a text specify the character of the universally demanded activities, among which lifting and digging are outstanding.[18]

In imperial China every commoner family was expected on demand to provide labour for hydraulic and other public services. The political and legal writings of India indicate a similar claim on corviable labour.[19] The laws of Inca Peru obliged all able-bodied men to render *corvée* service.[20] In ancient Mexico both commoner and upper-class adolescents were instructed in the techniques of digging and damming.[21] At times the masters of this hydraulic area levied the manpower of several territorial states for their gigantic hydraulic enterprises.[22]

In 19th-century Egypt 'the whole corviable population' worked in four huge shifts on Mehmed Ali's hydraulic installations. Each group laboured on the canals for 45 days until, after 180 days, the job was completed.[23] From 1881 on, at a time of decay and disintegration, 'the *whole* of the corvée fell on the poorest classes',[24] the smaller number being compensated for by an increase in the labour-time to 90 days. In some regions the conscripts were kept busy 'for 180 days'.[25]

b. Integration

Orderly cooperation involves planned integration. Such integration is especially necessary when the objectives are elaborate and the cooperating teams large.

Above the tribal level, hydraulic activities are usually comprehensive. Most writers who mention the cooperative aspect of hydraulic agriculture think in the main of digging, dredging and damming; and the organizational tasks involved in these labours is certainly considerable. But the planners of a major hydraulic enterprise are confronted with problems of a much more complex kind. How many persons are needed? And where can such persons be found? On the basis of previously made registers, the planners must determine the quota and criteria of selection. Notification follows selection, and mobilization notification. The assembled groups frequently proceed in quasimilitary columns. Having reached their destination, the buck privates of the hydraulic army must be distributed in proper numbers and according to whatever division of operations (spading, carrying of mud, etc.) is customary. If raw materials such as straw, faggots, lumber or stone have to be procured, auxiliary operations are organized; and if the work teams – *in toto* or in part – must be provided with food and drink, still other ways of appropriation, transport and distribution have to be developed. Even in its simplest form, agrohydraulic operations necessitate substantial integrative action. In their more elaborate variations, they involve extensive and complex organizational planning.

c. Leadership

All teamwork requires team leaders; and the work of large integrated teams requires on-the-spot leaders and disciplinarians as well as overall organizers and planners. The great enterprises of hydraulic agriculture involve both types of direction. The foreman usually performs no menial work at all; and except for a few engineering specialists the sergeants and officers of the labour force are essentially organizers.

To be sure, the physical element – including threats of punishment and actual coercion – is never absent. But here, if anywhere, recorded experience and calculated foresight are crucial. It is the circumspection, resourcefulness and integrative skill of the supreme leader and his aides which play the decisive role in initiating, accomplishing and perpetuating the major works of hydraulic economy.

d. Hydraulic leadership – political leadership

The effective management of these works involves an organizational web which covers either the whole, or at least the dynamic core, of the country's population. In consequence, those who control this network are uniquely prepared to wield supreme political power.

From the standpoint of the historical effect, it makes no difference whether the heads of a hydraulic government were originally peace chiefs, war leaders, priests, priest-chiefs or hydraulic officials *sans phrase*. Among the Chagga, the hydraulic corvée is called into action by the same horn that traditionally rallied the tribesmen for war.[26] Among the Pueblo Indians the war chiefs (or priests), although subordinated to the *cacique* (the supreme chief), direct and supervise the communal activities.[27] The early hydraulic city states of Mesopotamia seem to have been for the most part ruled by priest-kings. In China the legendary trail blazer of governmental water control, the Great Yü, is said to have risen from the rank of a supreme hydraulic functionary to that of king, becoming, according to protohistorical records, the founder of the first hereditary dynasty, Hsia.

No matter whether traditionally nonhydraulic leaders initiated or seized the incipient hydraulic 'apparatus', or whether the masters of this apparatus became the motive force behind all important public functions,[28] there can be no doubt that in all these cases the resulting regime was decisively shaped by the leadership and social control required by hydraulic agriculture.

B. Heavy Water Works and Heavy Industry

With regard to operational form, hydraulic agriculture exhibits important similarities to heavy industry. Both types of economic activities are preparatory to the ultimate processes of production. Both provide the workers with essential material for these ultimate processes. And both tend to be comprehensive, 'heavy'. For these reasons the large enterprises of hydraulic agriculture may be designated as 'heavy water works'.

But the dissimilarities are as illuminating as the similarities. The heavy water works of hydraulic agriculture and the heavy industry of modern economy are distinguished by a number of basic differences, which, properly defined, may aid us in more clearly recognizing the peculiarities of hydraulic society.

Heavy water works feed the ultimate agrarian producer one crucial auxiliary material: water; heavy industry provides auxiliary and raw materials of various kinds, including tools for finishing and heavy industry. Heavy water works fulfil important protective functions for the country at large; the protective installations (buildings, etc.) of industry do not. Heavy water works cover at their inception a relatively large area; and with the development of the hydraulic order they are usually spread still further. The operations of heavy industry are spatially much more restricted. At first, and for a number of preliminary processes, they may depend on small and dispersed shops; with the growth of the industrial order they tend to merge into one, or a few, major establishments.

The character of the labour force varies with these spatial and operational differences. Heavy water works are best served by a widely distributed personnel, whereas heavy industry requires the workers to reside near the locally restricted 'big' enterprises which employ them. The hydraulic demand is satisfied by adult peasant males, who continue to reside in their respective villages; whereas the industrial demand is satisfied by a geographically concentrated labour force.

The bulk of the hydraulic workers are expected to remain peasants, and in most cases they are mobilized for a relatively short period only – at best for a few days, at worst for any time that will not destroy their agricultural usefulness. Thus division of agrohydraulic labour is not accompanied by a corresponding division of labourers.

The contrast to the labour policy of heavy industry is manifest. Different from heavy water works, which may be created and maintained during a fraction of the year, heavy industry operates most effectively when it operates continuously. The industrial employers prefer to occupy their personnel throughout the year; and with the growth of the industrial system full-time labour became the rule. Thus division of industrial labour moves toward a more or less complete division of labourers.

The two sectors are also differently administered. In the main, modern heavy industry is directed by private owners or managers. The heavy water works of hydraulic agriculture are directed essentially by the government. The government also engages in certain other large enterprises, which, in varying combinations, supplement the agrohydraulic economy proper.

C. Calendar Making and Astronomy – Important Functions of the Hydraulic Regime

Among the intellectual functions fulfilled by the leaders of agrohydraulic activities, some are only indirectly connected with the organization of men and material; but the relation is highly significant nevertheless. Time keeping and calendar making are essential for the success of all hydraulic economies; and under special conditions special operations of measuring and calculating may be urgently needed.[29] The way in which these tasks are executed affect both the political and the cultural development of hydraulic society.

To be sure, man is deeply concerned about the swing of the seasons under all forms of extractive economy and throughout the agrarian world. But in most cases he is content to determine in a general way when spring or summer begin, when cold will set in, when rain or snow will fall. In hydraulic civilizations such general knowledge is insufficient. In areas of full aridity it is crucial to be prepared for the rise of the rivers whose overflow, properly handled, brings fertility and life and whose unchecked waters leave death and devastation in their wake. The dykes have to be repaired in the proper season so that they will hold in times of inundation; and the canals have to be cleaned so that the moisture will be satisfactorily distributed. In semi-arid areas receiving a limited or uneven rainfall an accurate calendar is similarly important. Only when the embankments, canals and reservoirs are ready and in good condition can the scanty precipitation be fully utilized.

The need for reallocating the periodically flooded fields and determining the dimension and bulk of hydraulic and other structures provide continual stimulation for developments in geometry and arithmetic. Herodotus ascribes the beginnings of geometry in Egypt to the need for annually remeasuring the inundated land.[30]

No matter whether the earliest scientific steps in this direction were made in the Nile Valley or in Mesopotamia, the basic correlation is eminently plausible. Obviously the pioneers and masters of hydraulic civilization were singularly well equipped to lay the foundations for two major and interrelated sciences: astronomy and mathematics.

As a rule, the operations of time keeping and scientific measuring and counting were performed by official dignitaries or by priestly (or secular) specialists attached to the hydraulic regime. Wrapped in a cloak of magic and astrology and hedged with profound secrecy, these mathematical and astronomical operations became the means both for improving hydraulic production and bulwarking the superior power of the hydraulic leaders.

D. Further Construction Activities Customary in Hydraulic Societies

The masters of the hydraulic state did not confine their activities to matters immediately connected with agriculture. The methods of cooperation which were so effective in the sphere of crop-raising were easily applied to a variety of other large tasks.

Certain types of works are likely to precede others. Generally speaking, the irrigation canal is older than the navigation canal; and hydraulic digging and damming occurred prior to the building of highways. But often derivative steps were taken before the original activities had progressed far, and different regional conditions favoured different evolutionary sequences. Thus the divergencies of interaction and growth are great. They include many constructional activities above and beyond the sphere of hydraulic agriculture.[31]

1. Nonagrarian hydraulic works

a. Aqueducts and reservoirs providing drinking water

A commonwealth able to transfer water for purposes of irrigation readily applies its hydraulic know-how to the providing of drinking water. The need for such action was slight in the greater part of Medieval Europe, where the annual precipitation furnished sufficient ground water for the wells on which most towns depended for their water supply.[32]

Even in the hydraulic world, drinking water is not necessarily an issue. Wherever rivers, streams or springs carry enough moisture to satisfy the drinking needs of the population throughout the year, no major problem arises. The inhabitants of the Nile and Ganges Valleys and of many similar areas did not have to construct elaborate aqueducts for this purpose.

The irregular flow of rivers or streams or the relatively easy access to fresh and clear mountain water has stimulated in many hydraulic landscapes the construction of comprehensive installations for the storage and distribution of drinking water. In America great aqueducts were built by the hydraulic civilizations of the Andean zone and Meso-America.[33] The many reservoirs (tanks) of Southern India frequently serve several uses; but near the large residential centres the providing of drinking water is usually paramount. In certain areas of the Near East, such as Syria and Assyria, brilliantly designed aqueducts have satisfied the water needs of many famous cities, Tyre,[34] Antioch[35] and Nineveh[36] among them. In the Western world of rainfall agriculture, aqueducts were built primarily by such Mediterranean peoples as the Greeks and the Romans, who since the dawn of history maintained contact with – and learned from – the technically advanced countries of Western Asia and North Africa. No doubt the Greeks and Romans would have been able to solve their drinking-water problem without inspiration from the outside; but the form of their answer strongly suggests the influence of Oriental engineering.[37]

b. Navigation canals

Among the great agrarian conformations of history, only hydraulic society has constructed navigation canals of any major size. The seafaring Greeks, making the Mediterranean their highway, avoided an issue which the ancient city states were poorly equipped to handle. The not-too-numerous Roman canals were apparently all dug at a time when the growing Orientalization of the governmental apparatus stimulated, among other things, a growing interest in all kinds of public works.[38]

The rainfall farmers of Medieval Europe, like their counterparts elsewhere, shunned rather than sought the marshy river lowlands. And their feudal masters paid little attention to the condition of the watercourses, for which they had no use. Still less did they feel obliged to construct additional and artificial rivers – canals. Few if any important canals were built during the Middle Ages,[39] and medieval trade and transport were seriously handicapped by the state of the navigable rivers.[40]

It was in connection with the rise of a governmentally encouraged commercial and industrial capitalism that the West began to build canals on a conspicuous scale. The 'pioneer of the canals of modern Europe', the French Canal du Midi, was completed only in the second half of the 17th century, in 1681,[41] that is, little more than a century before the end of the absolutist regime. And in the classical country of inland navigation, England,[42] 'little … was done in making canals … until the middle of the eighteenth century'[43] – that is, until a time well after the close of England's absolutist period and immediately prior to the beginning of the machine age.

As stated above, the members of a hydraulic commonwealth felt quite differently about the management of natural and artificial watercourses. They approached the fertility-bearing rivers as closely as possible, and in doing so they had to find ways of draining the lowland marshes and strengthening and reshaping the river banks. Naturally the question of inland navigation did not arise everywhere. Existing rivers and streams might be suitable for irrigation, but not for shipping (Pueblos, Chagga, Highland Peru); or the ocean might prove an ideal means of transportation (Hawaii, Coastal Peru). In certain localities inland navigation was satisfactorily served by man-managed rivers (Egypt, India) and lakes (Mexico) plus whatever irrigation canals were large enough to accommodate boats (Mesopotamia).

But when supplementary watercourses were not only possible but desirable, the organizers of agrohydraulic works had little difficulty in utilizing their cooperative 'apparatus' to make them available. The new canals might be only minor additions to the existing watercourses. The ancient Egyptians constructed canals in order to circumnavigate impassable cataracts, and they temporarily connected the Nile and the Red Sea;[44] but these enterprises had little effect on the overall pattern of the country's hydraulic economy. In other instances, navigation canals assumed great importance. They satisfied the needs of the masters of the hydraulic state: the transfer of parts of the agrarian surplus to the administrative centres and the transport of messengers and troops.

In Thailand (Siam) the different hydraulic tasks overlapped. In addition to the various types of productive and protective hydraulic installations, the government constructed in the centres of rice production and state power a number of canals, which essentially served as 'waterways', that is, as a means for transporting the rice surplus to the capital.[45]

The corresponding development in China is particularly well documented. In the large plains of North China the beginnings of navigation canals go back to the days of the territorial states – that is, to the period prior to 221 BC, when the various regional governments were still administered by officials who were given office lands in payment for their services. The difference between the state-centred system of land grants as it prevailed in early China and the knighthood feudalism of Medieval Europe is spectacularly demonstrated by the almost complete absence of public works in feudal Europe and the enormous development of such works – hydraulic and otherwise – in the territorial states of China.[46]

The geographical and administrative unification of China which vastly increased the political need for navigation canals also increased the state's organizational power to build them. The first centuries of the empire saw a great advance not only in the construction of irrigation canals,[47] reservoirs, and protective river dikes but also in the digging of long canals for administrative and fiscal purposes.[48]

When, after several centuries of political fragmentation, the Sui rulers at the end of the 6th century again unified 'all-under-heaven', they bulwarked the new political structure by creating out of earlier and substantial beginnings the gigantic Imperial Canal, significantly known in China as Yün Ho, 'the Transport Canal'. This canal extends today for about 800 miles, its length equalling the distance from the American-Canadian Great Lakes to the Gulf of Mexico or – in European terms – the distance from Berlin to Bordeaux or from Hamburg to Rome. For labour on part of this gigantic water work the Sui government mobilized in the regions north of the Yellow River alone 'more than a million of men and women',[49] that is, almost one-half of the total population which England is said to have had from the 14th to the 16th century.[50]

The gigantic effort involved in banking the rivers and building the canals of China is indicated by the American agronomist, F. H. King, who conservatively estimates the combined lengths of the man-managed watercourses of China, Korea and Japan at some 200,000 miles. 'Forty canals across the United States from east to west and sixty from north to south would not equal in number of miles those in these three countries today. Indeed, it is probable that this estimate is not too large for China alone.'[51]

2. Large nonhydraulic constructions

a. Huge defence structures

The need for comprehensive works of defence arises almost as soon as hydraulic agriculture is practised. Contrary to the rainfall farmer, who may shift his fields with relative ease, the irrigation farmer finds himself depending on an unmovable, if highly rewarding, source of fertility. In the early days of hydraulic cultivation reliance on a fixed system of water supply must in many cases have driven the agrarian community to build strong defences around its homes and fields.

For this purpose hydraulic agriculture proved suggestive in two ways: it taught man how to handle all kinds of building materials, earth, stone, timber, etc., and it trained him to manipulate these materials in an organized way. The builders of canals and dams easily became the builders of trenches, towers, palisades and extended defence walls.

In this, as in all corresponding cases, the character and magnitude of the operations were determined by internal and external circumstances. Surrounded by aggressive neighbours, the Pueblo Indians ingeniously utilized whatever building material was at hand to protect their settlements, which rarely comprised more than a few hundred inhabitants.[52] The fortress-like quality of their villages is manifest to the present-day anthropologist; it struck the Spanish *conquistadores*, who were forced at times to besiege a single settlement for days and weeks before they could take it.[53] Rigid cooperation assured security of residence, just as it assured success in farming. An early observer stresses this aspect of Pueblo life: 'They all work together to build the villages.'[54]

The Chagga were equally effective in the transfer of their hydraulic work patterns to military constructions. Their great chieftain, Horombo (*fl.* 1830), used 'thousands of people' to build great fortifications, which in part still stand today.[55] 'The walls of these fortifications are some six feet high, and in length 305 yards on the south side, 443 yards on the north, 277 yards on the east side, and 137 yards on the west side.'[56] Tunnels, extended trenches and dugouts added to the defence of the walled settlements, which appeared early in the history of the Chagga.[57]

'Deep dugouts excavated under the huts, and often leading into underground passages with outlets at some distance, were used for refuge. Almost every country was secured with great war trenches, which are everywhere to be seen at the present day and are often still of great depth.'[58]

These instances show what even primitive hydraulic societies could achieve in the field of defence construction, when they strained their cooperative resources to the full. Higher hydraulic societies employed and varied the basic principle in accordance with technical and institutional circumstances.

In pre-Columbian Mexico the absence of suitable labour animals placed a limitation on transport, and while this restricted siege craft, it did not preclude the struggle for or the defence of the cities. In emergencies many government-built hydraulic works in the main lake area fulfilled military functions, just as the monster palaces and temples served as bastions against an invading enemy.[59] Recent research draws attention to various types of Mexican forts and defence walls.[60] Because of their size and importance, they may safely be adjudged as state-directed enterprises. The colossal fortresses and walls of pre-Spanish Peru, which astonished early and recent observers,[61] are known to have been built at the order of the government and by 'incredibly' large teams of corvée labourers.[62]

Many texts and pictorial representations have portrayed the walls, gates and towers of ancient Egypt, Sumer, Babylonia, Assyria and Syria. The *Arthashāstra* indicates the systematic manner in which the rulers of the first great Indian empire treated problems of fortification and defence.[63] At the dawn of Chinese history new capitals were created at the ruler's command, and during the last centuries of the Chou period the territorial states used their corviable manpower to wall entire frontier regions, not only against the tribal barbarians but also against each other. In the 3rd century BC the unifier of China, Ch'in Shih Huang-ti, linked together and elaborated older territorial structures to form the longest unbroken defence installation ever made by man.[64] The periodic reconstruction of the Chinese Great Wall expresses the continued effectiveness of hydraulic economy and government-directed mass labour.

b. Roads

The existence of government-made highways is suggested for the Babylonian period;[65] it is documented for Assyria.[66] And the relationship between these early constructions and the roads of Persia, the Hellenistic states and Rome seems 'beyond doubt'.[67] The great Persian 'royal road' deeply impressed the contemporary Greeks;[68] it served as a model for the Hellenistic rulers,[69] whose efforts in turn inspired the official road builders of the Roman empire.[70] According to Mez, the Arabs inherited 'the type of "governmental road", like its name, from the Persian "Royal Road".'[71] Beyond this, however, they showed little interest in maintaining good roads, probably because they continued to rely in the main on camel caravans for purposes of transport. The later Muslim regimes of the Near East used highways, but they never restored them to the state of technical perfection which characterized the pre-Arab period.[72]

Roads were a serious concern of India's vigorous Maurya kings.[73] A 'royal road' of 10,000 *stadia*, which is said to have led from the capital to the north-western border, had a system of marking distances which, in a modified form, was again employed by the Mogul emperors.[74] In Southern India, where Hindu civilization was perpetuated for centuries after the north had been conquered, government-made roads are mentioned in the inscriptions; and 'some of them are called king's highways'.[75] The Muslim rulers of India continued the Indian rather than the West Asian pattern in their effort to maintain a network of state roads.[76] Sher Shāh (*d.* 1545) built four great roads, one of which ran from Bengal to Agra, Delhi and Lahore.[77] Akbar is said to have been inspired by Sher Shāh when he built a new 'king's highway', called the Long Walk, which for 400 miles was 'shaded by great trees on both sides'.[78]

In China, a gigantic network of highways was constructed immediately after the establishment of the empire in 221 BC. But in this case, as in the cases of the irrigation and navigation canals or the long defence walls, the imperial engineers systematized and elaborated only what their territorial predecessors had initiated. Long before the 3rd century BC an efficient territorial state was expected to have well kept overland highways, supervised by central and local officials, lined with trees, and provided with stations and guest houses.[79] Under the empire, great state roads connected all the important centres of the northern core area with the capital. According to the official *History of the Han Dynasty*, the First Emperor

> built the Imperial Road throughout the empire. To the east it stretched to Yen and Ch'i and to the south it reached Wu and Ch'u. The banks and the shore of the Chiang [the Yangtze River] and the lakes and the littoral along the sea coast were all made accessible. The highway was fifty paces wide. A space three *chang* [approximately twenty-two feet] wide in the center was set apart by trees. The two sides were firmly built, and metal bars were used to reinforce them. Green pine trees were planted along it. He constructed the Imperial Highway with such a degree of elegance that later generations were even unable to find a crooked path upon which to place their feet.[80]

In the subsequent dynasties the building and maintenance of the great trunk roads and their many regional branches remained a standard task of China's central and local administration.

The rugged terrain of Meso-America and the absence of fully coordinated empires seems to have discouraged the construction of highways during the pre-Columbian period, at least on the high plateau. But the Andean area was the scene of extraordinary road building. The Spanish conquerors described in detail the fine highways which crossed both the coastal plain and the highlands and which formed connecting links between them.[81] Commenting on the Andean roads, Hernando Pizarro writes he never saw their like in similar terrain 'within the entire Christian world'.[82] In fact the only parallel he could think of was the system of highways built by the Romans. The similarity is telling. As we shall discuss below, the extensive Roman roads were the fruits of a fateful transformation that made the Roman Empire a Hellenistically (Orientally) despotic state.

The efforts required to build all these great highways have attracted much less attention than the finished products. But what evidence we have indicates that like most other major government enterprises, they were mainly executed through the cooperative effort of state-levied corvée labourers. Under the Inca empire supervisory officials marked off the land and informed the local inhabitants 'that they should make these roads'. And this was done with little cost to the government. The commandeered men 'come with their food and tools to make them'.[83]

The highways of imperial China required an enormous labour force for their construction and a very sizable one for their maintenance. A Han inscription notes that the construction of a certain highway in the years AD 63–66 occupied 766,800 men. Of this great number only 2690 were convicts.[84]

c. Palaces, capital cities and tombs

A governmental apparatus capable of executing all these hydraulic and nonhydraulic works could easily be used in building palaces and pleasure grounds for the ruler and his court, palace-like government edifices for his aides, and monuments and tombs for the distinguished dead. It could be used wherever the equalitarian conditions of a primitive tribal society yielded to tribal or no-longer tribal forms of autocracy.

The head chief of a Pueblo community had his fields worked for him by the villagers. But apparently his dwelling did not differ from the houses of other tribesmen, except perhaps that it was better and more securely located. The Chagga chieftains had veritable palaces erected for their personal use; and the corvée labour involved in their construction was substantial.[85]

The colossal palaces of the rulers of ancient Peru were erected by the integrated manpower of many labourers. In pre-Columbian Mexico, Nezahualcoyotzin, the king of Tezcuco, the second largest country in the Aztec Federation, is said to have employed more than 200,000 workers each day for the building of his magnificent palace and park.[86]

Unlimited control over the labour power of their subjects enabled the rulers of Sumer, Babylon and Egypt to build their spectacular palaces, gardens and tombs. The same work pattern prevailed in the many smaller states that shaped their government on the Mesopotamian or Egyptian model. According to the biblical records, King Solomon built his beautiful temple with labour teams that, like those of Babylonia, were kept at work for four months of the year.[87]

The great edifices of Mogul India have been frequently described. Less known but equally worthy of mention are the constructions of the earlier periods. The third ruler of the Tughluq, Fīrūs Shāh (*ca.* 1308–1388), dug several important irrigation canals, the famous 'Old Jumna Canal' among them. He built forts, palaces, and palace-cities, mosques and tombs. The palace-fort of Kotla Fīrūs Shāh, which rose in his new capital of Fīrūsābād (Delhi), faithfully preserved the grand style of pre-Islamic Indian and Eastern architecture.[88]

The Chinese variant of the general agromanagerial building trend is revealed in many elaborate works. The First Emperor of China, Ch'in Shih Huang-ti, began to build great hydraulic works in the early days of his power; and in the course of his reign he completed colossal works of the nonhydraulic public and semi-private types. Having destroyed all his territorial rivals, he constructed the previously mentioned network of highways which gave his officials, messengers and troops easy access to all regions of his far-flung empire. Later he defended himself against the northern pastoralists by consolidating the Great Wall. Palaces for his personal use had been built in the early days of his reign; but it was only in 213 BC that work was begun on his superpalace. This monster project, together with the construction of his enormous tomb,[89] is said to have occupied work teams numbering over 700,000 persons.[90]

Eight hundred years later the second monarch of a reunified China, Emperor Yang (604–17) of the Sui Dynasty, mobilized a still larger labour force for the execution of similar monster enterprises. In addition to the more than 1 million persons – men and women – levied for the making of the Grand Canal,[91] he dispatched huge corvée teams to extend the imperial roads[92] and to work on the Great Wall. According to the *History of the Sui Dynasty*, over a million persons toiled at the Great Wall.[93] According to the same official source, the construction of the new eastern capital, which included a gigantic new imperial palace, involved no less than 2 million people 'every month'.[94]

d. Temples

The position, fate and prestige of the secular masters of hydraulic society were closely interlinked with that of their divine protectors. Without exception, the political rulers were eager to confirm and bulwark their own legitimacy and majesty by underlining the greatness of their supernatural supporters. Whether the government was headed by secular monarchs or priest-kings, the commanding centre made every effort to provide the supreme gods and their earthly functionaries with adequate surroundings for worship and residence.

Government-directed work teams, which erected gigantic palaces, were equally fitted to erect gigantic temples. Ancient inscriptions note the many temples built by the Mesopotamian rulers.[95] Usually the sovereign speaks as if these achievements resulted solely from his personal efforts. But occasional remarks indicate the presence of 'the people' who toiled 'according to the established plan'.[96] Similarly, most Pharaonic texts refer to the final achievement[97] or to the greatness of the directing sovereign;[98] but again a number of texts refer to the government-led labour forces, 'the people'.[99]

In the agromanagerial cultures of pre-Columbian America, buildings for religious purposes were particularly conspicuous. Native tradition as well as the early Spanish accounts emphasize the tremendous labour required to construct and maintain the sacred houses and pyramids. The Mexicans coordinated their communal energies to erect the first temple for the newly established island city, the later Aztec capital;[100] and their increasingly powerful descendants mobilized the manpower of many subjugated countries for the construction of increasingly huge temples.[101] The city-like palace of the famous King of Tezcuco, Nezahualcoyotzin, contained no less than 40 temples.[102] The great number of labourers engaged in building this palace- and temple-city has already been cited. Like the monster work teams of Mexico, those of Tezcuco could draw upon the entire corviable population.[103] In another country of the main lake region, Cuauhtitlan, the construction of large-scale hydraulic works[104] was followed by the building of a great temple. It took 13 years to complete the second task.[105]

In the Andean zone, as in most other areas of the hydraulic world, the attachment of the priesthood to the government is beyond doubt. The Incas made heavy levies on their empire's material wealth in order to beautify their temples and pyramids.[106] They called up whatever manpower was needed to collect the raw material, transport it and do the actual work of construction.[107]

E. The Masters of Hydraulic Society – Great Builders

Evidently the masters of hydraulic society, whether they ruled in the Near East, India, China or pre-Conquest America, were great builders. The formula is usually invoked for both the aesthetic and the technical aspect of the matter; and these two aspects are indeed closely interrelated. We shall briefly discuss both of them with regard to the following types of hydraulic and nonhydraulic construction works:

- I. Hydraulic works
    - A. Productive installations
      (Canals, aqueducts, reservoirs, sluices and dikes for the purpose of irrigation)
    - B. Protective installations
      (Drainage canals and dikes for flood control)
    - C. Aqueducts providing drinking water
    - D. Navigation canals
- II. Nonhydraulic works
    - A. Works of defence and communication
        1. Walls and other structures of defence
        2. Highways
    - B. Edifices serving the public and personal needs of the secular and religious masters of hydraulic society
        1. Palaces and capital cities
        2. Tombs
        3. Temples

1. The aesthetic aspect

a. Uneven conspicuousness

The majority of persons who have commented on the great builders of Asia and ancient America are far more articulate on the nonhydraulic than on the hydraulic achievements. Within the hydraulic sphere more attention is again given to the aqueducts for drinking water and the navigation canals than to the productive and protective installations of hydraulic agriculture. In fact, these last are frequently overlooked altogether. Among the nonhydraulic works, the 'big houses' of power and worship and the tombs of the great are much more carefully investigated than are the large installations of communication and defence.

This uneven treatment of the monster constructions of hydraulic society is no accident. For functional, aesthetic and social reasons the hydraulic works are usually less impressive than the nonhydraulic constructions. And similar reasons encourage uneven treatment also within each of the two main categories.

Functionally speaking, irrigation canals and protective embankments are widely and monotonously spread over the landscape, whereas the palaces, tombs and temples are spatially concentrated. Aesthetically speaking, most of the hydraulic works are undertaken primarily for utilitarian purposes, whereas the residences of the rulers and priests, the houses of worship and the tombs of the great are meant to be beautiful. Socially speaking, those who organize the distribution of manpower and material are the same persons who particularly and directly enjoy the benefits of many nonhydraulic structures. In consequence they are eager to invest a maximum of aesthetic effort in these structures (palaces, temples and capital cities) and a minimum of such effort in all other works.

Of course, the contrast is not absolute. Some irrigation works, dikes, aqueducts, navigation canals, highways and defence walls do achieve considerable functional beauty. And closeness to the centres of power may lead the officials in charge to construct embankments, aqueducts, highways, bridges, walls, gates and towers with as much care for aesthetic detail as material and labour permit.

But these secondary tendencies do not alter the two basic facts that the majority of all hydraulic and nonhydraulic public works are aesthetically less conspicuous than the royal and official palaces, temples and tombs, and that the most important of all hydraulic works – the canals and dykes – from the standpoint of art and artistry are the least spectacular of all.

b. The monumental style

Such discrepancies notwithstanding, the palaces, government buildings, temples and tombs share one feature with the 'public' works proper: they, too, tend to be large. The architectural style of hydraulic society is monumental.

This style is apparent in the fortress-like settlements of the Pueblo Indians. It is conspicuous in the palaces, temple cities and fortresses of ancient Middle and South America. It characterizes the tombs, palace-cities, temples and royal monuments of Pharaonic Egypt and ancient Mesopotamia. No one who has ever observed the city gates and walls of a Chinese capital, such as Peking, or who has walked through the immense palace gates and squares of the Forbidden City to enter its equally immense court buildings, ancestral temples and private residences can fail to be awed by their monumental design.

Pyramids and dome-shaped tombs manifest most consistently the monumental style of hydraulic building. They achieve their aesthetic effect with a minimum of ideas and a maximum of material. The pyramid is little more than a huge pile of symmetrically arranged stones.

The property-based and increasingly individualistic society of ancient Greece loosened up the massive architecture, which had emerged in the quasihydraulic Mycenaean period.[108] During the later part of the first millennium BC, when Alexander and his successors ruled the entire Near East, the architectural concepts of Hellas transformed and refined the hydraulic style without, however, destroying its monumental quality.

In Islamic architecture the two styles blended to create a third. The products of this development were as spectacular in the western-most outpost of Islamic culture – Moorish Spain – as they were in the great eastern centres: Cairo, Baghdad, Bukhara, Samarkand and Istanbul. The Taj Mahal of Agra and kindred buildings show the same forces at work in India, a subcontinent which, before the Islamic invasion, had evolved a rich monumental architecture of its own.

c. The institutional meaning

It hardly needs to be said that other agrarian civilizations also combined architectural beauty with magnitude. But the hydraulic rulers differed from the secular and priestly lords of the ancient and medieval West, first because their constructional operations penetrated more spheres of life, and second because control over the entire country's labour power and material enabled them to attain much more monumental results.

The scattered operations of rainfall farming did not involve the establishment of national patterns of cooperation, as did hydraulic agriculture. The many manorial centres of Europe's knighthood society gave rise to as many fortified residences (castles); and their size was limited by the number of the attached serfs. The king, being little more than the most important feudal lord, had to build his castles with whatever labour force his personal domain provided.

The concentration of revenue in the regional or territorial centres of ecclesiastical authority permitted the creation of the largest individual medieval edifices: churches, abbeys and cathedrals. It may be noted that these buildings were erected by an institution which, in contrast to all other prominent Western bodies, combined feudal with quasihydraulic patterns of organization and acquisition.

With regard to social control and natural resources, however, the master builders of the hydraulic state had no equal in the nonhydraulic world. The modest Tower of London and the dispersed castles of medieval Europe express the balanced baronial society of the Magna Carta as clearly as the huge administrative cities and colossal palaces, temples and tombs of Asia, Egypt and ancient America express the organizational coordination and the mobilization potential of hydraulic economy and statecraft.[109]

F. The Bulk of All Large Nonconstructional Industrial Enterprises Managed also by The Hydraulic Government

1. A comparative view

A government capable of handling all major hydraulic and nonhydraulic construction may, if it desires, play a leading role also in the nonconstructional branches of industry. There are 'feeding' industries, such as mining, quarrying, salt gathering, etc.; and there are finishing industries, such as the manufacture of weapons, textiles, chariots, furniture, etc. Insofar as the activities in these two spheres proceeded on a large scale, they were for the most part either directly managed or monopolistically controlled by the hydraulic governments. Under the conditions of Pharaonic Egypt and Inca Peru, direct management prevailed. Under more differentiated social conditions, the government tended to leave part of mining, salt gathering, etc. to heavily taxed and carefully supervised entrepreneurs, while it continued to manage directly most of the large manufacturing workshops.

By combining these facts with what we know of the hydraulic and nonhydraulic constructional operations of the state, we may in the following table indicate the managerial position of the hydraulic state both in agriculture and industry. For purposes of comparison, we include corresponding data from two other agrarian societies and from mercantilist Europe.

Table 7.1 *Government management in the spheres of agriculture and industry*

Institutional conformations	*AGRICULTURE*		*INDUSTRY*			
	Heavy waterworks	*Farming*	*Mining, etc.*	*Construction industry*	*Manufacturing*	
					Large shops	*Small shops*
Hydraulic society	**+**	–	(+)[1]	**+**[2]	+	–
Coastal city states of classical Greece	–	–	–	–	–	–
Medieval Europe	–	(+)[3]	–	(+)[3]	(+)[3]	–
Mercantilist Europe	–	–	(–)	–	–	–

Key

+ Predominant
+ Outstandingly significant
– Irrelevant or absent
( ) Trend limited or modified by factors indicated in the text

1. Simpler conditions
2. On a national scale
3. On a manorial scale

In ancient Greece, mining was mainly in the hands of licensed businessmen. As long as the concessionaire delivered a fixed part of his output to the state, he enjoyed 'very extensive' rights; he 'was said to "buy" the mine, he organized the working as he pleased, the ore was his, and he could cede his concession to a third party'.[110] In Medieval Europe mining was also essentially left to private entrepreneurs, who, having obtained a concession from the royal or territorial authorities, proceeded independently and mostly through craft cooperatives.[111] The mercantilist governments of Europe operated some mines directly; but the majority was managed by strictly supervised private owners.[112]

All these arrangements differ profoundly from the system of government mining prevailing in Pharaonic Egypt and Inca Peru. Mercantilist usage resembles in form, but not in institutional substance, the policy pursued in certain of the more differentiated hydraulic societies, where government operation of some mines was combined with private, but government-licensed, handling of others.[113]

Except for mining, Oriental and Occidental absolutism are less similar in the industrial sphere than has been claimed, whereas a resemblance of sorts does exist between hydraulic society and feudal Europe. In hydraulic society, the majority of the not-too-many larger industrial workshops was government managed. In the mercantilist Occident they were, under varying forms of state supervision, predominantly owned and run by private entrepreneurs. In the coastal city-states of classical Greece the government was neither equipped nor inclined to engage in industrial activities. The rulers of medieval Europe, faced with a different situation, proceeded differently. In their manorial workshops they employed a number of serf-artisans, who were kept busy satisfying the needs of their masters. The feudal lords also summoned serf labour for the construction of 'big houses' – castles. The similarity between this manorial system of cooperative work and the hydraulic pattern is evident. But again the functional similarity is limited by the differences in the societal setting. The medieval kings and barons could dispose only over the labour force of their own domains and estates, while the hydraulic rulers could draw on the unskilled and skilled labour of large territories, and ultimately on that of the whole country.

The decisive difference, however, between hydraulic society and the three civilizations with which we compare it lies, insofar as industry is concerned, in the sphere of construction. It is this sphere which more than any other sector of industry demonstrates the organizational power of hydraulic society. And it is this sphere which achieved results never attained by any other agrarian or mercantilist society.

The full institutional significance of this fact becomes apparent as soon as we connect it with the corresponding agrarian development. Government-managed heavy waterworks place the large-scale feeding apparatus of agriculture in the hands of the state. Government-managed construction works make the state the undisputed master of the most comprehensive sector of large-scale industry. In the two main spheres of production the state occupied an unrivalled position of operational leadership and organizational control.

2. The power of the hydraulic state over labour greater than that of capitalist enterprises

In both spheres the hydraulic state levied and controlled the needed labour forces by coercive methods that were invocable by a feudal lord only within a restricted area, and that were altogether different from the methods customary under capitalist conditions. The hydraulic rulers were sufficiently strong to do on a national scale what a feudal sovereign or lord could accomplish only within the borders of his domain. They compelled able-bodied commoners to work for them through the agency of the corvée.

Corvée labour is forced labour. But unlike slave labour, which is demanded permanently, corvée labour is conscripted on a temporary, although recurring, basis. After the corvée service is completed, the worker is expected to go home and continue with his own business.

Thus the corvée labourer is freer than the slave. But he is less free than a wage labourer. He does not enjoy the bargaining advantages of the labour market, and this is the case even if the state gives him food (in the ancient Near East often 'bread and beer') or some cash. In areas with a highly developed money economy the hydraulic government may levy a corvée tax and hire rather than conscript the needed labour. This was done largely in China at the close of the Ming dynasty and during the greater part of Ch'ing rule.

But there as elsewhere the government arbitrarily fixed the wage. And it always kept the workers under quasimilitary discipline.[114] Except in times of open political crisis, the hydraulic state could always muster the labor forces it required; and this whether the workers were levied or hired. It has been said that the Mogul ruler Akbar, 'by his *firmān* (order) could collect any number of men he liked. There was no limit to his massing of labourers, save the number of people in his Empire.'[115] *Mutatis mutandis*, this statement is valid for all hydraulic civilizations.

G. A Genuine and Specific Type of Managerial Regime

Thus the hydraulic state fulfilled a variety of important managerial functions.[116] In most instances it maintained crucial hydraulic works, appearing in the agrarian sphere as the sole operator of large preparatory and protective enterprises. And usually it also controlled the major nonhydraulic industrial enterprises, especially large constructions. This was the case even in certain 'marginal' areas, where the hydraulic works were insignificant.

The hydraulic state differs from the modern total managerial states in that it is based on agriculture and operates only part of the country's economy. It differs from the laissez-faire states of a private-property-based industrial society in that, in its core form, it fulfils crucial economic functions by means of commandeered (forced) labour.

Notes

1 For early formulations of this view see Smith, 1937: 6; Mill, 1909: 131, 144; Marx, 1890–1894, I: 300, 322 ff. Modern economists have perpetuated and even sharpened them. Writes Seligman (1914: 350): 'In the immense domain of agricultural production the possibility of combination is almost entirely eliminated.' And Marshall (1946: 290): 'In agriculture there is not much division of labour, and there is no production on a very large scale.'

2 For the concept of 'previous or preparatory labor' see Mill, 1909: 29, 31. The general principle was already indicated by Smith (1937), who, when discussing the division of operations in industry, pointed to the 'growers of the flax and the wool' and the miners as providers of raw material (5 ff., 11), to the spinners and weavers as engaged in special processing operations (6), and to the makers of tools as combining elements of both procedures (11). Mill (1909: 36 ff.) also includes, in the category of previous labour, activities aimed at protecting industrial production proper.

28 Rüstow, who in general accepts Kern's view concerning the correlation between large-scale and government-directed water control and the centralized and despotic character of the state in ancient Egypt and Mesopotamia, assumes that in these areas nomadic conquerors developed the hydraulic works *after* establishing conquest empires (Rüstow, 1950–1952, I: 306).
Patterns of leadership and discipline traditional to conquering groups could be, and probably were, invoked in establishing certain hydraulic governments; but Pueblo, Chagga and Hawaiian society show that such formative patterns could also be endogenous. In any case, the ethnographic and historical facts point to a multiple rather than a single origin for hydraulic societies.

31 Anyone interested in studying the technical and organizational details of a major hydraulic order may consult Willcocks's admirable description of irrigation and flood control in 19th-century Egypt (Willcocks, 1889: *passim*). A comprehensive survey of the hydraulic conditions in India at the close of the 19th century has been made by the Indian Irrigation Commission (RRCAI). In my study of Chinese economics and society I have systematically analysed the ecological foundations and the various aspects of China's traditional hydraulic order (Wittfogel, 1931: 61–93, 188–300, and 410–456). Today we also have an archaeological account of the growth of hydraulic and other constructions over time and for a limited, but evidently, representative area: the Virú Valley in Peru (see Willey, 1953: 344–389).

46 Previously I viewed Chou China as a feudal society exhibiting Oriental features, which appeared early and became increasingly conspicuous until, at the close of the period, they prevailed completely (Wittfogel, 1931: 278 ff.; *ibid*., 1935: 40 ff.). The idea of a society that crosses the institutional divide is entirely compatible with the findings of the present inquiry; and by interpreting Chou society in this way, I would not have had to change a long-held position. But intensified comparative studies compel me to change. The arid and semi-arid settings of North China (17 inches annual rainfall in the old Chou domain and 24 inches in the domain of the pre-Chou dynasty, Shang) suggest hydraulic agriculture for the ancient core areas. The lay of the land, the summer floods, and the periodic silting-up of the rivers necessitated comprehensive measures of flood control especially in the heartland of Shang power. A realistic interpretation of legends and protohistorical sources (cf. Wittfogel and Goldfrank, 1943: *passim*) points to the rise of a hydraulic way of life long before the Shang dynasty, whose artifacts (bronzes) and inscriptions reflect a highly developed agrarian civilization with refined techniques of record keeping, calculations and astronomy. The recognizable institutions of early Chou are those of a hydraulic society, which gradually intensified its managerial and bureaucratic 'density'. The Chou sovereigns behaved toward the territorial rulers not as the first among equals but as supreme masters responsible only to Heaven. It was not their fault that their despotic claims, which possibly imitated Shang precedents, were realized imperfectly and with decreasing effect. In contrast, the rulers of the territorial states were strong enough to proceed absolutistically within their respective realms. The lands that they assigned were given not in a contractual way and to independently organized (corporated) knights and barons, but to office holders and persons permitted to enjoy sinecures. They were not fiefs but office lands.

50 Kulischer, 1928–1929, II: 6.
51 King, 1927: 97 ff.
52 Castañeda, 1896: 512. Bandelier upholds Castañeda's figures against divergent statements made in other early Spanish sources (Bandelier, 1890&1892, I: 120 ff. and nn.; cf. *ibid.*, 1929&1930: 312, 46 ff., 171–173).
53 Castañeda, who was the official chronicler of the first Spanish expedition, notes (1896: 494) that the defence towers of a large Zuni settlement were equipped with 'embrassures and loopholes … for defending the roofs of the different stories'. He adds, 'The roofs have to be reached first, and these upper houses are the means of defending them.' The experiences of the second expedition confirmed and supplemented the initial observations. Gallegos concludes his remarks concerning Pueblo building by referring to the movable wooden ladders 'by means of which they climb to their quarters'. At night 'they lift them up since they wage war with one another' (Gallegos, 1927: 265). Obregon also stresses the military value of the ladders; in addition, he explains how the edifices themselves served to protect the community: 'These houses have walls and loopholes from which they defend themselves and attack their enemies in their battles' (Obregon, 1928: 293).
One of Coronado's lieutenants, approaching certain Tigua settlements, 'found the villages closed by palisades'. The Pueblos, whose inhabitants had been subjected to various forms of extortion and insult 'were all ready for fighting. Nothing could be done, because they would not come down onto the plain and the villages are so strong that the Spaniards could not dislodge them.' Attacking a hostile village, the Spanish soldiers reached the upper story by surprise tactics. They remained in this dangerous position for a whole day, unable to prevail until the Mexican Indians, who accompanied them, approached the Pueblo from below, digging their way in and smoking out the defenders (Castañeda, 1896: 496. For a discussion of Castañeda's report see Bandelier, 1929&1930: 38 ff.).
Besieging a large Tigua settlement, Coronado's men had an opportunity to test thoroughly the defence potential of a Pueblo which was not taken by surprise: 'As the enemy had had several days to provide themselves with stores, they threw down such quantities of rocks upon our men that many of them were laid down, and they wounded nearly a hundred with arrows.' The siege lasted for seven weeks. During this time, the Spaniards made several assaults; but they were unable to take the Pueblo. The villagers eventually abandoned their fortress-like bulwark, not because the aggressors had penetrated their defences, but because of lack of water (Castañeda, 1896: 498 ff.; cf. RDS, 1896: 576). Bandelier supplements Castañeda's report of this significant event by an account given by Mota Padilla, an 18th-century author, who claims to have had access to the original writings of still another member of Coronado's staff (Bandelier, 1929&1930: 323). Mota Padilla's version contains a number of details which reveal the techniques of attack as well as the strength and ingenuity of the defence. Some of the Spaniards 'reached the top of the wall, but there they found that the natives had removed the roofs of many (upper) rooms, so that there was no communication between them, and as there were little towers at short distances from each other, from which missiles were showered upon the assailants on the top, the Spaniards had more than 60 of their number hurt, three of whom died of their wounds' (*ibid.*, 48).
54 Castañeda (1896: 520) qualifies this general statement by saying that the women were 'engaged in making the [adobe] mixture and the walls, while the men bring the wood and put it in place'. Modern reports assign the above duties to the men and credit them in addition with erecting the walls, the construction labours of the women being confined to plastering (White, 1932: 33; cf. Parsons, 1932: 212). The divergence between the early and recent descriptions may reflect an actual institutional change or merely a difference in the accuracy of observation. While interesting to the anthropologist, this discrepancy does not affect our basic conclusions regarding the communal character of large-scale building in the American Pueblos.

114 Boulais, 1924: 728.
115 Pant, 1930: 70.
116 Social science is indebted to James Burnham for pointing to the power potential inherent in managerial control. The present inquiry stresses the importance of the general (political) organizer as compared not only to the technical specialist (see Veblen, 1945: 441 ff.), but also to the economic manager. This, however, does not diminish the author's appreciation of the contribution made by Burnham through his concept of managerial leadership.

Marcus Cato on Agriculture

Marcus Porcius Cato

It is true that to obtain money by trade is sometimes more profitable, were it not so hazardous; and likewise money-lending, if it were as honourable. Our ancestors held this view and embodied it in their laws, which required that the thief be mulcted double and the usurer fourfold; how much less desirable a citizen they considered the usurer than the thief, one may judge from this. And when they would praise a worthy man their praise took this form: 'good husbandman', 'good farmer'; one so praised was thought to have received the greatest commendation. The trader I consider to be an energetic man, and one bent on making money; but, as I said above, it is a dangerous career and one subject to disaster. On the other hand, it is from the farming class that the bravest men and the sturdiest soldiers come, their calling is most highly respected, their livelihood is most assured and is looked on with the least hostility, and those who are engaged in that pursuit are least inclined to be disaffected. And now, to come back to my subject, the above will serve as an introduction to what I have undertaken.

I. When you are thinking of acquiring a farm, keep in mind these points: that you be not over-eager in buying nor spare your pains in examining, and that you consider it not sufficient to go over it once. However often you go, a good piece of land will please you more at each visit. Notice how the neighbours keep up their places; if the district is good, they should be well kept. Go in and keep your eyes open, so that you may be able to find your way out. It should have a good climate, not subject to storms; the soil should be good, and naturally strong. If possible, it should lie at the foot of a mountain and face south; the situation should be healthful, there should be a good supply of labourers, it should be well watered, and near it there should be a flourishing town, or the sea, or a navigable stream, or a good and much travelled road. It should lie among those farms which do not often change owners; where those who have sold farms are sorry to have done so. It should be well furnished with buildings. Do not be hasty in despising the methods of management

adopted by others.[1] It will be better to purchase from an owner who is a good farmer and a good builder. When you reach the steading, observe whether there are numerous oil presses and wine vats; if there are not, you may infer that the amount of the yield is in proportion. The farm should be one of no great equipment, but should be well situated. See that it be equipped as economically as possible, and that the land be not extravagant. Remember that a farm is like a man – however great the income, if there is extravagance but little is left. If you ask me what is the best kind of farm, I should say: a hundred iugera[2] of land, comprising all sorts of soils, and in a good situation; a vineyard comes first if it produces bountifully wine of a good quality; second, a watered garden; third, an osier-bed; fourth, an oliveyard; fifth, a meadow; sixth, grain land;[3] seventh, a wood lot; eighth, an arbustum;[4] ninth, a mast grove.[5]

II. When the master arrives at the farmstead, after paying his respects to the god of the household, let him go over the whole farm, if possible, on the same day; if not, at least on the next. When he has learned the condition of the farm, what work has been accomplished and what remains to be done, let him call in his overseer the next day and inquire of him what part of the work has been completed, what has been left undone; whether what has been finished was done betimes, and whether it is possible to complete the rest; and what was the yield of wine, grain and all other products. Having gone into this, he should make a calculation of the labourers and the time consumed. If the amount of work does not seem satisfactory, the overseer claims that he has done his best, but that the slaves have not been well, the weather has been bad, slaves have run away, he has had public work[6] to do; when he has given these and many other excuses, call the overseer back to your estimate of the work done and the hands employed. If it has been a rainy season, remind him of the work that could have been done on rainy days: scrubbing and pitching wine vats, cleaning the farmstead, shifting grain, hauling out manure, making a manure pit, cleaning seed, mending old harness and making new; and that the hands ought to have mended their smocks and hoods. Remind him, also, that on feast days old ditches might have been cleaned, road work done, brambles cut, the garden spaded, a meadow cleared, faggots bundled, thorns rooted out, spelt ground and general cleaning done. When the slaves were sick, such large rations should not have been issued. After this has been gone into calmly, give orders for the completion of what work remains; run over the cash accounts, grain accounts and purchases of fodder; run over the wine accounts, the oil accounts – what has been sold, what collected, balance due and what is left that is saleable; where security for an account should be taken, let it be taken; and let the supplies on hand be checked over. Give orders that whatever may be lacking for the current year be supplied; that what is superfluous be sold; that whatever work should be let out be let. Give directions as to what work you want done on the place, and what you want let out,[7] and leave the directions in writing. Look over the live stock and hold a sale. Sell your oil, if the price is satisfactory, and sell the surplus of your wine and grain. Sell worn-out oxen, blemished cattle, blemished sheep, wool, hides, an old wagon, old tools, an old slave, a sickly slave and whatever else is superfluous. The master should have the selling habit, not the buying habit.

III. In his youth the owner should devote his attention to planting. He should think a long time about building, but planting is a thing not to be thought about but done. When you reach the age of thirty-six you should build, if you have your land planted.[8] In building, you should see that the steading does not lag behind the farm nor the farm behind the steading. It is well for the master to have a well-built barn[9] and storage room and plenty of vats for oil and wine, so that he may hold his products for good prices; it will redound to his wealth, his self-respect and his reputation. He should have good presses, so that the work may be done thoroughly. Let the olives be pressed immediately after gathering, to prevent the oil from spoiling. Remember that high winds come every year and are apt to beat off the olives; if you gather them at once and the presses are ready, there will be no loss on account of the storm, and the oil will be greener and better. If the olives remain too long on the ground or the floor they will spoil, and the oil will be rancid. Any sort of olive will produce a good and greener oil if it is pressed betimes. For an oliveyard of 120 iugera there should be two pressing equipments, if the trees are vigorous, thickly planted and well cultivated. The mills should be stout and of different sizes, so that if the stones become worn you may change. Each should have its own leather ropes, six sets of hand bars, six double sets of pins and leather belts. Greek blocks run on double ropes of Spanish broom; you can work more rapidly with eight pulleys above, and six below; if you wish to use wheels it will work more slowly but with less effort.

IV. Have good stalls, stout pens and latticed feed-racks. The rack bars should be a foot apart; if you make them in this way the cattle will not scatter their feed. Build your dwelling-house in accordance with your means. If you build substantially on a good farm, placing the house in a good situation, so that you can live comfortably in the country, you will like to visit it, and will do so oftener; the farm will improve, there will be less wrongdoing, and you will receive greater returns; the forehead is better than the hindhead.[10] Be a good neighbour, and do not let your people commit offences. If you are popular in the neighbourhood it will be easier for you to sell your produce, easier to let out your work,[11] easier to secure extra hands. If you build, the neighbours will help you with their work, their teams, and their materials; if trouble comes upon you, which God forbid,[12] they will be glad to stand by you.

V. The following are the duties of the overseer: He must show good management. The feast days must be observed. He must withhold his hands from another's goods and diligently preserve his own. He must settle disputes among the slaves; and if anyone commits an offence he must punish him properly in proportion to the fault. He must see that the servants are well provided for, and that they do not suffer from cold or hunger. Let him keep them busy with their work – he will more easily keep them from wrongdoing and meddling. If the overseer sets his face against wrongdoing, they will not do it; if he allows it, the master must not let him go unpunished. He must express his appreciation of good work, so that others may take pleasure in well-doing. The overseer must not be a gadabout, he must always be sober, and must not go out to dine. He must keep the servants busy, and see that the master's orders are carried out.

He must not assume that he knows more than the master. He must consider the master's friends his own friends. He must pay heed to anyone to whom he has been bidden to listen. He must perform no religious rites, except on the occasion of the Compitalia[13] at the cross-roads, or before the hearth. He must extend credit to no one without orders from the master, and must collect the loans made by the master. He must lend to no one seed-grain, fodder, spelt, wine or oil. He must have two or three households, no more, from whom he borrows and to whom he lends. He must make up accounts with the master often. He must not hire the same day-labourer or servant or caretaker for longer than a day. He must not want to make any purchases without the knowledge of the master, nor want to keep anything hidden from the master. He must have no hanger-on. He must not consult a fortune-teller, or prophet or diviner or astrologer.[14] He must not stint the seed for sowing, for that brings bad fortune. He must see to it that he knows how to perform all the operations of the farm, and actually does perform them often, but not to the extent of becoming exhausted; by so doing he will learn what is in his servants' minds, and they will perform their work more contentedly. Also, he will be less disposed to gad about, will be in better health, and will enjoy his sleep more. He must be the first out of bed, the last to go to bed. Before then he must see that the farmstead is closed, that each one is asleep in his proper place, and that the stock have fodder.

See that the draft oxen are looked after with the greatest care, and be somewhat indulgent to the teamsters to make them look after their stock with more pleasure. See that you keep your ploughs and ploughshares in good condition. Be careful not to plough land which is *cariosa*[15] or drive a cart over it, or turn cattle into it; if you are not careful about this, you will lose three years' crop of the land on which you have turned them. Litter the cattle and flocks carefully, and see that their hoofs are kept clean. Guard against the scab in flocks and herds; it is usually caused by under-feeding and exposure to wet weather. See that you carry out all farm operations betimes, for this is the way with farming: if you are late in doing one thing you will be late in doing everything. If bedding runs short, gather oak leaves and use them for bedding down sheep and cattle. See that you have a large dunghill; save the manure carefully, and when you carry it out, clean it of foreign matter and break it up. Autumn is the time to haul it out. During the autumn also dig trenches around the olive trees and manure them. Cut poplar, elm and oak leaves betimes; store them before they are entirely dry, as fodder for sheep. Second-crop hay and aftermath should also be stored dry. Sow turnips, forage crops and lupins after the autumn rains.

VI. This rule should be observed as to what you should plant in what places: Grain should be sown in heavy, rich, treeless soil; and if this sort of soil is subject to fogs it should preferably be sown with rape, turnips, millet and panic-grass. In heavy, warm soil plant olives[16] – those for pickling, the long variety, the Sallentine, the orcites, the posea, the Sergian, the Colminian and the waxy-white; choose especially the varieties which are commonly agreed to be the best for these districts. Plant this variety of olives at intervals of 25 or 30 feet. Land which is suitable for olive planting is that which faces the west and is exposed to the sun; no other will be good. Plant the Licinian olive in colder and thinner soil. If you plant it in heavy or warm soil the yield will be worthless, the tree will exhaust itself in bearing, and a reddish scale will injure it. Around the borders of the farm and along the roads plant elms and some poplars, so that you may have leaves for the sheep and cattle; and the timber will be available if you need it. Wherever there is a river bank or wet ground, plant poplar cuttings and a reed thicket. The method of planting is as follows: turn the ground with the mattock and then plant the eyes of the reed three feet apart. Plant there also the wild asparagus,[17] so that it may produce asparagus; for a reed thicket goes well with the wild asparagus, because it is worked and burned over, and furnishes a shade when shade is needed. Plant Greek willows along the border of the thicket, so that you may have withes for tying up vines.

Choose soil for laying out a vineyard by the following rules: In soil which is thought to be best adapted for grapes and which is exposed to the sun, plant the small Aminnian,[18] the double eugeneum and the small parti-coloured; in soil that is heavy or more subject to fogs plant the large Aminnian, the Murgentian, the Apician and the Lucanian. The other varieties, and especially the hybrids, grow well anywhere.

VII. It is especially desirable to have a plantation[19] on a suburban farm, so that firewood and faggots may be sold, and also may be furnished for the master's use. On the same farm should be planted anything adapted to the soil, and several varieties of grapes, such as the small and large Aminnian and the Apician. Grapes are preserved in grape-pulp in jars;[20] also they keep well in boiled wine, or must, or after-wine.[21] You may hang up the hard-berried and the larger Aminnian and they will keep as well dried before the forge fire as when spread in the sun. Plant or ingraft all kinds of fruit – sparrow-apples, Scantian and Quirinian quinces,[22] also other varieties for preserving, must-apples and pomegranates (the urine or dung of swine should be applied around the roots of these to serve as food for the fruit); of pears, the volema, the Anician frost-pears (these are excellent when preserved in boiled wine),[23] the Tarentine, the must-pear, the gourd-pear and as many other varieties as possible; of olives, the orcite and posea, which are excellent when preserved green in brine or bruised in mastic[24] oil. When the orcites are black and dry, powder them with salt for five days; then shake off the salt, and spread them in the sun for two days, or pack them in boiled must without salt. Preserve sorbs in boiled must; or you may dry them; make them quite free from moisture. Preserve pears in the same way.

VIII. Plant mariscan figs in chalky, open soil; the African, Herculanean, Saguntine, the winter variety, the black Tellanian with long pedicles, in soil which is richer or manured. Lay down a meadow, so that you may have a supply of hay – a water meadow if you have it, if not, a dry meadow. Near a town it is well to have a garden planted with all manner of vegetables, and all manner of flowers for garlands – Megarian bulbs, conjugulan myrtle,[25] white and black myrtle, Delphian, Cyprian, and wild laurel, smooth nuts, such as Abellan, Praenestine and Greek filberts. The suburban farm, and especially if it be the only one, should be laid out and planted as ingeniously as possible.

Marcus Terentius Varro on Agriculture

Marcus Terentius Varro

Book I

1. Had I possessed the leisure, Fundania,[1] I should write in a more serviceable form what now I must set forth as I can, reflecting that I must hasten; for if man is a bubble, as the proverb has it, all the more so is an old man. For my 80th year admonishes me to gather up my pack before I set forth from life. Wherefore, since you have bought an estate and wish to make it profitable by good cultivation, and ask that I concern myself with the matter, I will make the attempt; and in such wise as to advise you with regard to the proper practice not only while I live but even after my death. And I cannot allow the Sibyl to have uttered prophecies which benefited mankind not only while she lived, but even after she had passed away, and that too people whom she never knew – for so many years later we are wont officially to consult her books when we desire to know what we should do after some portent – and not do something, even while I am alive, to help my friends and kinsfolk. Therefore I shall write for you three handbooks to which you may turn whenever you wish to know, in a given case, how you ought to proceed in farming. And since, as we are told, the gods help those who call upon them, I will first invoke them – not the Muses, as Homer and Ennius do, but the 12 councillor-gods;[2] and I do not mean those urban gods, whose images stand around the forum, bedecked with gold, six male and a like number female, but those 12 gods who are the special patrons of husbandmen. First, then, I invoke Jupiter and Tellus, who, by means of the sky and the earth, embrace all the fruits of agriculture; and hence, as we are told that they are the universal parents, Jupiter is called 'the Father', and Tellus is called 'Mother Earth'. And second, Sol and Luna, whose courses are watched in all matters of planting and harvesting. Third, Ceres and Liber, because their fruits are most necessary for life; for it is by their favour that food and drink come from the farm. Fourth, Robigus and Flora; for when they are propitious the rust will not harm the grain and the trees, and they will not fail to bloom in their season; wherefore, in honour of Robigus has been established the solemn feast of the Robigalia, and in honour of Flora the games called Floralia. Likewise I beseech Minerva and Venus, of whom the one protects the oliveyard

and the other the garden; and in her honour the rustic Vinalia has been established.[3] And I shall not fail to pray also to Lympha and Bonus Eventus, since without moisture all tilling of the ground is parched and barren, and without success and 'good issue' it is not tillage but vexation. Having now duly invoked these divinities, I shall relate the conversations which we had recently about agriculture, from which you may learn what you ought to do; and if matters in which you are interested are not treated, I shall indicate the writers, both Greek and Roman, from whom you may learn them.

III. 'Well, then', said Agrasius, 'since we have decided the nature of the subjects which are to be excluded from agriculture, tell us whether the knowledge of those things used in agriculture is an art or not, and trace its course from starting-point to goal.' Glancing at Scrofa, Stolo said: 'You are our superior in age, in position, and in knowledge, so you ought to speak.' And he, nothing loath, began: 'In the first place, it is not only an art but an important and noble art. It is, as well, a science, which teaches what crops are to be planted in each kind of soil, and what operations are to be carried on, in order that the land may regularly produce the largest crops.

IV. 'Its elements are the same as those which Ennius says are the elements of the universe – water, earth, air and fire.[4] You should have some knowledge of these before you cast your seed, which is the first step in all production.[5] Equipped with this knowledge, the farmer should aim at two goals, profit and pleasure; the object of the first is material return, and of the second enjoyment. The profitable plays a more important role than the pleasurable; and yet for the most part the methods of cultivation which improve the aspect of the land, such as the planting of fruit and olive trees in rows, make it not only more profitable but also more saleable, and add to the value of the estate. For any man would rather pay more for a piece of land which is attractive than for one of the same value which, though profitable, is unsightly. Further, land which is more wholesome is more valuable, because on it the profit is certain; while, on the other hand, on land that is unwholesome, however rich it may be, misfortune does not permit the farmer to reap a profit. For where the reckoning is with death, not only is the profit uncertain, but also the life of the farmers; so that, lacking wholesomeness, agriculture becomes nothing else than a game of chance, in which the life and the property of the owner are at stake. And yet this risk can be lessened by science; for, granting that healthfulness, being a product of climate and soil, is not in our power but in that of nature, still it depends greatly on us, because we can, by care, lessen the evil effects. For if the farm is unwholesome on account of the nature of the land or the water, from the miasma which is exhaled in some spots; or if, on account of the climate, the land is too hot or the wind is not salubrious, these faults can be alleviated by the science and the outlay of the owner. The situation of the buildings, their size, the exposure of the galleries, the doors and the windows, are matters of the highest importance. Did not that famous physician, Hippocrates, during a great pestilence save not one farm but many cities by his skill?[6] But why do I cite him? Did not our friend Varro here, when the army and fleet were at Corcyra, and all the houses were crowded with the sick and the dead, by cutting new windows to admit the north wind, and shutting out the infected winds, by changing the position of doors, and other precautions of the same kind, bring back his comrades and his servants in good health?[7]

V. 'But as I have stated the origin and the limits of the science, it remains to determine the number of its divisions.' 'Really,' said Agrius, 'it seems to me that they are endless, when I read the many books of Theophrastus, those which are entitled "The History of Plants" and "The Causes of Vegetation".' 'His books,' replied Stolo, 'are not so well adapted to those who wish to tend land as to those who wish to attend the schools of the philosophers;[8] which is not to say that they do not contain matter which is both profitable and of general interest. So, then, do you rather explain to us the divisions of the subject.' 'The chief divisions of agriculture are four in number,' resumed Scrofa: 'First, a knowledge of the farm, comprising the nature of the soil and its constituents; second, the equipment needed for the operation of the farm in question; third, the operations to be carried out on the place in the way of tilling; and fourth, the proper season for each of these operations. Each of these four general divisions is divided into at least two subdivisions: the first comprises questions with regard to the soil as such, and those which pertain to housing and stabling. The second division, comprising the movable equipment which is needed for the cultivation of the farm, is also subdivided into two: the persons who are to do the farming, and the other equipment. The third, which covers operations, is subdivided: the plans to be made for each operation, and where each is to be carried on. The fourth, covering the seasons, is subdivided: those which are determined by the annual revolution of the sun, and those determined by the monthly revolution of the moon. I shall discuss first the four chief divisions, and then the eight subdivisions in more detail.

VI. 'First, then, with respect to the soil of the farm, four points must be considered: the conformation of the land, the quality of the soil, its extent, and in what way it is naturally protected. As there are two kinds of conformation, the natural and that which is added by cultivation, in the former case one piece of land being naturally good, another naturally bad, and in the latter case one being well tilled, another badly, I shall discuss first the natural conformation. There are, then, with respect to the topography, three simple types of land – plain, hill and mountain; though there is a fourth type consisting of a combination of these, as, for instance, on a farm which may contain two or three of those named, as may be seen in many places. Of these three simple types, undoubtedly a different system is applicable to the lowlands than to the mountains, because the former are hotter than the latter; and the same is true of hillsides, because they are more temperate than either the plains or the mountains. These qualities are more apparent in broad stretches, when they are uniform; thus the heat is greater where there are broad plains, and hence in Apulia the climate is hotter and more humid, while in mountain regions, as on Vesuvius, the air is lighter and therefore more wholesome. Those who live in the lowlands suffer more in summer; those who live in the uplands suffer more in winter; the same crops are planted earlier in the spring in the lowlands than in the uplands, and are harvested earlier, while both sowing and reaping come later in the uplands. Certain trees, such as the fir and the pine, flourish best and are sturdiest in the mountains on account of the cold climate, while the poplar and the willow thrive here where the climate is warmer; the arbute and the oak do better in the uplands, the almond and the mariscan fig in the lowlands. On the foothills the growth is nearer akin to that of the plains than to that of the mountains; on the higher hills the opposite is true. Owing to these three types of configuration different crops are planted, grain being considered best adapted to the plains, vines to the hills, and forests to the mountains. Usually the winter is better for those who live in the plains, because at that season the pastures are fresh, and pruning can be carried on in more comfort. On the other hand, the summer is better in the mountains, because there is abundant forage at that time, whereas it is dry in the plains, and the cultivation of the trees is more convenient because of the cooler air. A lowland farm that everywhere slopes regularly in one direction is better than one that is perfectly level, because the latter, having no outlet for the water, tends to become marshy. Even more unfavourable is one that is irregular, because pools are liable to form in the depressions. These points and the like have their differing importance for the cultivation of the three types of configuration.'

Notes

Marcus Cato on Agriculture

1 Others render, 'Be careful not rashly to refuse to learn from others.'

2 A iugerum is approximately two-thirds of an acre.

3 It is most significant that Cato places grain farming sixth in importance. The second Punic War had completely demoralized the Republic. The yeomanry had been conscripted and the fields desolated and burned. 'Roman farmers torn from their homes for years and demoralized by the camps were unable or unwilling to settle down into the quiet routine of agricultural life… Their farms passed into the hands of capitalists, and the rich lands of Italy fell back into pasture, and half-naked slaves tended herds of cattle' (Bosworth Smith, *Rome and Carthage*, p230). Grain farming was no longer profitable, and it had become the custom to import grain from Sicily and Africa. The new Rome that emerged from this horrible war centred around a nobility of wealth and was in a state of demoralization. Such a condition naturally caused the cultivation of grain to be less important than that of the vine, the olive, domestic vegetables or the rearing of cattle.

4 The word is used of a plantation of trees, to which the vines were 'wedded' or of an orchard. Columella gives a description, Book V, Chapter 6, but Cato seems not to use the word in the sense first given.

5 To furnish feed for livestock.

6 Possibly on the public roads, as in the French corvée.

7 It was the regular custom among the Romans to let out certain work by contract in contrast with the work that was done by the farm organization under the management of the overseer.

8 The 'planting' is, of course, of trees and vines.

9 See Columella, I, 6; but Cato's villa had only two units, the *villa urbana*, or dwelling-house, and the *villa rustica*, for all other purposes.

10 The content of this homely maxim appears in practically all the writers on agriculture, and has entered, in some form, into almost all proverbial wisdom. Perhaps its most popular modern form is taken from Poor Richard'a almanack: 'The eye of a master will do more work than both his hands.' Cf Columella, I, 1, 18; Pliny, N. H., XVIII, 31.

11 See note 7.

12 *bona salute* is merely a formula to avoid the evil omen of mentioning misfortune.

13 The festival held annually at the cross-roads, in honour of the Lares Compitales. It occurred soon after the Saturnalia, in December, on a day, or days appointed by the praetor.

14 Compare Horace's warning against 'meddling with Babylonian calculations' (*Odes*, I, II), and many others. Columella, I, 8, 6, emphasizes the warning.

15 The term is explained by Columella, II, 4, 5: 'that is, when after a long, dry spell, a light rain wets the surface but does not sink in.' The injunction is repeated there.

16 For a description of the various varieties of olives, see Columella, V, 8. The Romans were experts in plant selection, and developed distinct varieties of all the leading horticultural and field crops.

17 *Corruda*: identified in the 5th (?) cent. Herbal under the name of Pseudo-Apuleius (*Herb*., 84) as 'the wild asparagus which the Greeks call ορμινον or μνακανδον and by other names.'

18 See Columella, III, 2 for a detailed discussion of varieties of grapes. In Chapter 9 he returns to the discussion of the Aminnian, and remarks that these were 'almost the only varieties known to the ancients'.

19 Cf note 4.

20 Cf Varro, I, 54, 2.

21 A small or sharp wine made from the husks of grapes; cf Varro, I, 54, 3.

22 Cf Varro, I, 59, 1.

23 Cf Varro, I, 59, 3.

24 This resin from the mastic-tree is used also to flavour a distilled liquor used in various countries, as Turkey, Greece, etc.

25 Pliny says (XV, 122) that the name is perhaps derived from that for marriage (*coniugium*). The colours are those of the berries.

Marcus Terentius Varro on agriculture

1 Varro's wife.

2 In the Etrusco-Romish language of religion, the twelve superior deities who formed the common council of the gods, assembled by Jupiter. The word occurs only in this phrase. Their names are given by Ennius in the hexameters:

Juno, Vesta, Minerva, Ceres, Diana, Venus, Mars, Mercurius, Ioui', Neptunus, Vulcanus, Apollo.

3 The festival occurred on 19 August; and Varro tells us (*De Ling. Lat.*, VI, 16) that it was 'because at that time a temple was dedicated to Venus, and the protection of the garden is assigned to her'. But Ovid, *Fasti*, IV, 877f offers another explanation.

4 Ennius, *Epicharmus*, frag. III, aqua, terra, anima, sol.

5 *Quod initium fructuum oritur* is variously interpreted. The present editors believe that quod must refer to the nominal idea *iacere semina* derived from the preceding clause.

6 The incident is mentioned by Pliny, *N.H.*, VII, 123.

7 Pompey's forces lay at Corcyra before Pharsalia, and Varro had joined him after surrendering to Caesar in Spain.

8 It will be understood that the word covers the meaning of our 'scientist'.

Agroecological Farming Systems in China

Li Wenhua

The Philosophy and Technology Related to IFS in Ancient China

Though the term integrated farming system (IFS) has been formally used for no more than 30 years, some primitive philosophy and technologies for implementation of this system can be traced back to ancient times (Tang, 1988; Tang, 1990; Li, 1993; Zhang et al, 1996).

Influence of ancient philosophical ideas on development of IFS

For thousands of years, Chinese philosophers have pondered on the harmonious relationship between humans, nature and the environment. The *Tian Ren He Yi* theory (heaven/nature and human/society are merged into one unit) had great influence among Chinese people and formed the roots of China's IFS. The most vigorous and flourishing development of the integrated concept was in the Spring and Autumn to Warring States period (720–221 BC). A set of systematic principles for the management of the relationships between man and the environment was formulated. For example, in a famous treatise, *Zhou Yi* (The Book of Change), a brief but deeply philosophical concept of the holistic relationship between *Tian* (heaven or nature), *Di* (earth or resources) and *Ren* (humans or society) was described. Respect for *Dao-Li* (natural relationship with the universe, geography, climate, etc.), *Shi-Li* (planning and management of human activities, such as agriculture, warfare, politics, family and others), and *Qing-Li* (ecological ethics, psychology, motives and values towards the environment) became a general principle for managing all social and productive matters. The *Yin* and *Yang* theory (negative and positive forces interacting with each other and ecological relationships) and the *Wuxing* theory (five elements within a system and the interrelated movements between them) have been widely used in agriculture to reflect the relationship between different components.

In ancient China, the people have long used the terms of *Xiang Cheng* and *Xiang Ke* to express the positive and negative relationships between different components when they co-exist. Two or more of these can integrate to exert *Xi ang Cheng* for their mutual benefits, and to use *Xiang Ke* for living control. All these basic philosophical concepts have profound influence on the practice and formulation of IFS (Wang, 1996).

The beginnings of IFS in ancient China

In the course of China's long history of agriculture, a wealth of knowledge and theories have accumulated (Institute of the History of Natural Sciences, 1985; Guo et al, 1986; Tang, 1986; Liang, 1989). Archaeological evidence has revealed that the ancestors of the Chinese people inhabited forests where they sheltered from external hazards and lived on edible parts of wild plants and animals. In the New Stone Age (6000–8000 BC), the Chinese initiated fire farming in which forests were burned and seeds were directly sown in soil covered with the ash. Tillage farming arose later on the burned land and the ash was mixed with soil before planting. Grains or other crops were grown without external fertilizer. After several years the crop yield decreased remarkably, and cultivation would shift to another forest and the same practices were repeated. Such slash-and-burn cultivation is the oldest and most primitive form of ecoagriculture and was widely practised over a period of 6000–7000 years until the Xia Dynasty (2000–1600 BC) when there was a gradual shift to settled farming, except in some remote mountainous areas in south-western China and among some minorities such as the Du Long, Nu, Xi Wa and Yao.

Slash-and-burn was also widely used in silviculture, for reforestation and afforestation with Chinese fir (*Cunninghamia laceolata*) in southern China, for thousands of years. Farmers remove all ground cover, including small trees and shrubs in summer, burn them in autumn, level the ground to mix in the ashes in winter and then either plant seedlings or cuttings of fir trees with other crops in spring, or grow crops for one or two years before tree planting. In newly established fir stands, intercropping is also practised until crown closure. Such measures, used in the process of establishment of fir forests, are similar to the Taungya system developed for management of teak (*Tectona grandis*) stands in Myanmar in the mid-1800s. Interplanting of trees and crops, now known as agroforestry, originated in the Shang-West Zhou Dynasties (1600–800 BC), as the forested land of the plains was converted into cultivated land, and farmers planted trees in or around the crop fields. Some grew fruit trees, vegetables or bred domestic animals (Gui Mowen, 1990), whereas in the mountainous areas with fewer people and more forests, peasants cultivated cash crops in the forests or interplanted food crops during reforestation and afforestation. Since then, various forms of agroforestry–animal husbandry have been developed and improved with appropriate facilities and structures in accordance with local conditions, particularly in the Ming and Qing Dynasties (14th–19th centuries) (Liang, 1983).

According to historical records, in the latter part of the New Stone Age (2500–2100 BC), along with an increase in population, collapse of the clan society and the appearance of slavery, agriculture developed rapidly. Slash-and-burn was no longer the main farming system except in less-populated but abundantly forested and underdeveloped areas. Instead of nomadic farming, the slave owners allotted a portion of their land to each slave. The slaves no longer moved to forested land for cultivation but settled in one place where they engaged in farming permanently. The forests on hilly land were preserved as pasture or hunting sites. Settled farming in the Xia and Shang Dynasties (2000–1100 BC) became a force pushing agricultural development. By that time, people began to make and improve bronze and wooden agricultural tools; to use animal labour in farming; to grow different crops, such as rice, wheat, millet, sorghum and beans; to raise domestic animals such as horses, cattle, sheep, chickens, pigs; and to cultivate fruit trees, vegetables, mulberry trees (*Morus alba*) and flax. Thus appeared the embryonic form of management of multi-component farming which included agriculture, silviculture, animal husbandry and sericulture and laid the foundation for small self-sufficient household economy.

During the West Zhou Dynasty (1100–700 BC), the slavery system gradually collapsed, and a land tenancy system, the 'nine squares', was widely adopted, particularly in the northern China Plain, as described by Mensius (400 BC). Under this system, a large portion of land was divided into nine equal square areas, of which the eight on the edges were allotted to serfs, while the central one belonged to the landlord and was managed by the eight serfs for him. Thus private land ownership was gradually established and resulted in further development of self-sufficient small farmers in which the family was the production unit. In this unit, agriculture, animal husbandry, silviculture, sericulture and domestic handicrafts were developed simultaneously and formed the so-called 'man-farming, woman-weaving' rural economy. This scenario was recorded in the *Book of Songs* (800 BC): 'trespass not on my lane, break not my willow trees; leap not over my fence, pick not my mulberry leaves; intrude not into my garden, cut not my sandwood trees' (Li, 1993).

Agricultural policy during these periods advocated and encouraged comprehensive production for multiple purposes as an effective way to prosperity. Mensius (400 BC), in praise of the self-sufficient small farming economy, emphasized 'if a family owns a certain piece of land with mulberry trees around its house for breeding silkworms, domesticated animals raised in its yard for meat, and crop fields cultivated and managed properly for cereals, it will be prosperous and will not suffer from starvation' (Tang, 1986). He also said that 'If the forests are timely felled, then an abundant supply of timber and firewood is ensured, if the fishing net with relatively big holes is timely cast into the pond, then there will be no shortage of fish and turtle for use' (Zhang, 1992). These present a picture of a prosperous, diversified rural economy and a vivid sketch of pastoral peace.

In the Spring–Autumn (770–481 BC) and Warring States (490–220 BC) Dynasties, a more sophisticated system of integrated farming developed. In the *Guan* Zi, written in the Warring States period, it was recorded that 'food will be plentiful, if five kinds of cereal crops were planted, the people would be satisfied if animals were raised, and the farmers would be enriched if mulberry and economic crops were planted'. This multi-planting system with effective use of time was reported in the *Xun* Zi published in the Warring States period. Many examples were recorded which showed the order in time of multi-harvest plantation.

Thoughts and practices from the Qin to the Tang Dynasty

History next witnessed the unification and fall of the Qin Dynasty (221–207 BC) and the decades of warring between Chu and Han States (210–105 BC). We are lucky to be able to find a number of systematic agriculture treatises from that time. Some contain valuable ideas and primitive concepts of ecological agriculture. Among the extant comprehensive works on agriculture, the four essays in *Lu Shi Chun Qiu* (Master Lu's Spring and Autumn Annals), namely, *Shen Nong* (Lay Stress on Agriculture), *Ren Di* (Capacity of Soil), *Bian Tu* (Work on Ground) and *Shen Shi* (Fitness of the Season) completed in 239 BC, can be claimed as the earliest agricultural treatises. *Lu Shi Chun Qiu* was written collectively by scholars who were guests at the house of Lu Buwei, the first prime minister of Qin. The above-mentioned essays are not independent specialized writings on agriculture, but together form a systematic and complete set of treatises. If *Shen Nong* deals mainly with the importance of promoting agricultural production at a political level, emphasizing agriculture as the root and industry and commerce as the branches, then the three essays *Ren Di*, *Bian Tu* and *Shen Shi* were devoted solely to agronomy. The three sum up the experiences of agricultural production of the labouring people before the Qin Dynasty and include a series of profound ideas and techniques for promoting productivity and conservation of natural resources and the environment.

At the beginning of the Han Dynasty, society became stable and the population grew steadily to 40 million. Experience accumulated from the past was collated, revised and much extended to serve as a guideline for agricultural policy making. In the Western Han Dynasty (206 BC–AD 24), *Fan Sheng Zhi Shu* (The Book of Fan Shengzhi) sums up the basic principles of farming in northern China. It gives an accurate description of the cultivation techniques, of the main crops and cash tree species, such as spiked millet, glutinous millet, winter wheat, spring wheat, rice, lesser beans and soya, female hemp, common perilla, male hemp, melon, gourd, taro and mulberry. The so-called *San Yi* principle was formulated by that time, as stated in *Huai Nan Zi* (The Book of Huai Nan Zi, about 100 BC). Since ancient times, those who want to become masters of the people were exorted to make the best use of time and land plus human labour for production. Consequently, crops flourished, domestic animals thrived, trees were timely planted, and fields were regularly worked. Mulberry trees and hemp were grown on fertile soil, while on hilly and steep mountain slopes unsuitable for crop growing, trees were planted for timber and firewood.

Therefore, each site was used for appropriate production and 'to fish where water is rich, to forest where mountain is dominant, to raise livestock where forage is abundant, to plant crops where land is arable', and to guide year-round activities with 24 solar subseasons in order to synchronize these activities with the climate. Such timely and well arranged multi-component activities resulted in enormous economic benefits. (Institute of the History of Natural Sciences, 1985).

Among the Chinese classics, *Qi Min Yao Shu* (Essential Farming Skills of the People of Qi), written by Jia Sixie some 1400 years ago, is the best preserved and most comprehensive. Jia Sixie's attitude towards writing *Qi Min Yao Shu* was very serious. According to his own account, he gathered a large amount of data from classic and contemporary writings, collected many proverbs and folksongs, made inquiries from experts and drew from personal experience. The book embraces farming, forestry, animal husbandry, sideline production and fishery in an area comprising today's southeastern Shanxi, central–south Hebei, part of Henan, north of the Huanghe (Yellow) River, and Shandong. Consisting of 110,000 words, the book covered a wide range of knowledge of agriculture including detailed description of rotation and intercropping systems, as well as a wealth of useful knowledge on the improvement of soil fertility and soil and water conservation. In accordance with the characteristics of crops, he distinguished those that could be rotted from those that could not. He also provided a set of rotation methods and pointed out that plants of the bean family were the best forerunner crops for improving soil fertility. He remarked that 'For spiked millet, it is best to sow in soils following mung bean or lesser bean, or to sow panicled millet or sesame in soil following hemp, and least successful to sow in soil that has been planted to turnip.' The Chinese labouring people have rich experience in breeding varieties of crops/vegetables for a fixed cultivation system. The term 'garden-style cultivation' or 'gardenization' is sometimes used to describe this multi-component system. The *Qi Min Yao Shu* mentioned that mallow (*Malva verticillata*, called *kui* in ancient China) can be sown three times and that chives were harvested not more than five times a year, indicating that the vegetation was sown and harvested continually on one piece of land. Sowing coriander and scallion or lesser beans among melon-vines and growing coriander and green onion together suggests that interplanting was practised in the cultivation of vegetables at that time (Fan Chuyu, 1984).

Qi Min Yao Shu also provides, in its 'Miscellany', notes on growing a large variety of vegetables: near the cities and towns, more melons, fruits and eggplants should be grown, as what is not consumed by the family can easily be sold. If there are 10*mu* (1*mu* equals 1/15ha or roughly 1/6 acre) of land, pick out the five that are most fertile. Use 2.5*mu* to grow green onion and the other half to sow sundry vegetables like gourds, radish, mallow, lettuce, turnip, white pea, lesser bean and eggplant in the second, fourth, sixth, seventh and eighth month, respectively (Dong Kaichen, 1984). The chapter *Zhong Sang Zhe* (Mulberry Cultivation) in *Qi Min Yao Shu* described the experience of intercropping mulberry with bean and other crops. The seedlings of mulberry tree were first grown in a nursery 5 feet apart and then replanted 10*bu* apart (approximately 7–8m). If beans and appropriate crops are cultivated between mulberry, the space can be fully utilized, while the fertility of the soil can be improved. However, the intercropping of mulberry with maize and sorgum or millet will be harmful to the soil. Radish can be grown within 60cm of the trees. When the radish are harvested, pigs can be put in to feed on the residues of crops and to loosen the soil. Jia Sixie affirmed the role of green manure in soil improvement, and suggested that the best way is to plough in mung beans, then lesser beans and sesame. In brief, *Qi Min Yao Shu* is not only rich in content, it is detailed and accurate. It sums up the vast amount of agricultural knowledge accumulated in China before the 6th century, with a deep understanding of the interrelationship between crops and their environment and implementation of the knowledge in agricultural practice.

China is the country which first raised silkworms, planted mulberry trees and wove the wonderful silk fabric. Silk culture existed in China 4000 years ago, the embryo of IFS had appeared in the Shang–Zhou period (1600–1100 BC), and records of the Han Dynasty (206 BC– AD 220) mention sericulture in the *Can Shu* (Books on Silkworm Raising) and *Zhong Shu Cang Guo Xiang Can* (How to Plant Trees, Store Fruits and Judge Silkworm). Unfortunately, none of these has come down to us. In the more than 2000 years since the Han Dynasty, however, a number of ancient books discussing sericulture have been handed down. Some are monographs; others devote chapters to sericulture. In the techniques of sericulture, not only the integration of mulberry cultivation with silkworm raising was included, but the methods of cultivation of different types of mulberry in cooperation with other plants. For instance, *Fan Sheng Zhi Shu* tells how to grow mulberry trees: 'In the first year, sow a mixture of mulberry seeds and glutinous millet. When the mulberry plants are as high as the millet, cut them down with a sickle close to the ground. Next spring mulberry suckers will spring out. Such mulberry trees are convenient for plucking and management because of their shortness.' Through continuous efforts and improvement by farmers in different periods, sericulture, together with animal husbandry or fishery, has become the major 'sideline' production in the self-sufficient rural economy. Handicraft industries, including silk reeling, spinning and weaving, also rapidly developed. Around 200 BC silk from China made its way to middle and western Asia and Europe along a route that became known as the Silk Road (Institute of the History of Natural Sciences, 1985). In the *Nong Sang Tong Jue* (Handbook for Farming and Mulberry) it is said that 'among the nine prefectures, each field is different in its landscape, water condition and climate. Different crop varieties are suitable for different fields.' It was recorded in the *Xia Zhou Shu* that 'The following is law: To cut the trees on the mountain in spring is forbidden, fishing is forbidden in water areas during summer.' This was the first law for the protection of natural resources. In the *Huainan Tzi*, it was also pointed out that 'Those pregnant cannot be killed; those in egg stage cannot be fetched; fish shorter than 12 inches cannot be caught; pigs younger than one year should not be eaten.'

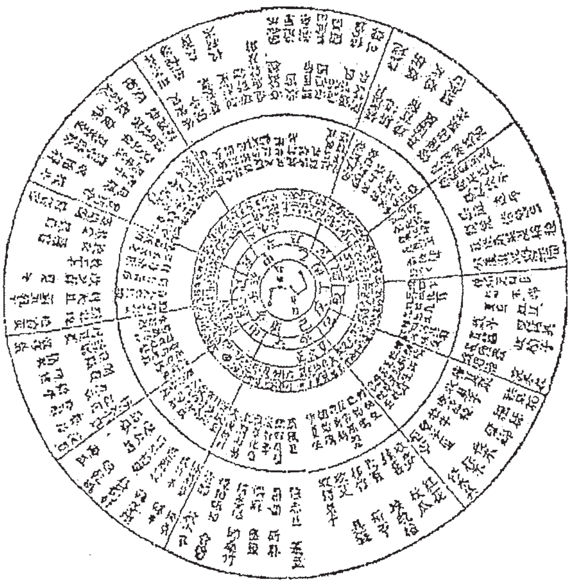
Thoughts and practices from the Tang to the Yuan Dynasty

A well-known paper on comprehensive agriculture, *Chen Fu Nong Shu* (Agricultural Treatise of Chen Fu), was completed in 1149 in the Southern Song Dynasty (1127–1179). In spite of its small size (only 12,500 words), it is substantial in content. This ancient treatise systematically discussed land utilization, giving priority to agricultural techniques of the rice-growing regions south of the Changjiang (Yangtze) River. The author provides a general view of intercropping and preservation of soil fertility using comprehensive measures.

Multi-component systems were recorded in *Wang Zheng Nong Shu* (Agricultural Treatise by Wang Zheng) in the Yuan Dynasty (1271–1368). Wang Zheng was a local administrative officer in the area now called Anhui and Jiangxi, who often visited rural areas for inspections and was very interested in agricultural production. This treatise sums up the production practice of dry farmland cultivation in the Yellow River plain and paddy-rice cultivation in the Yangtze River Basin. Its present edition has about 110,000 words and is divided into three parts: *Nong Song Tong Jue* (General Survey of Agriculture and Silviculture), *Bai Gu Pu* (Guide to a Hundred Cereals), and *Nong Qi Tu Pu* (A Collection of Illustrative Plates for Agricultural Implements). Wang Zheng summarized the various technologies and experiences in farming, forestry, animal husbandry, sideline production and fishery and discussed the fitness of season and soil. The farming chart is a praiseworthy creation of Wang Zheng: ingeniously combining constellation periodicity, seasons, natural signs and procedures of agricultural production into an organic whole, it puts together all the main points of *Nong Jia Yue Ling* (Monthly Ordinances for Farmers) and sums them up in a small chart which is clear, definite, handy and very practical (Figure 9.1).

Another example is fishery in paddy fields. In *Ling Biao Lu Yi*, written during the Tang Dynasty, it was described that 'putting the eggs of grass carp into paddy fields, when fish grow up, the roots of weeds were eaten up and the field is fertilized. Consequently the rice can yield a good harvest.'

Another excellent example of Chinese people in development of traditional ecological farming is the now world-famous dyke-pond system, or so-called integrated agriculture–aquaculture system (Zhong et al, 1987). China has a long history of mulberry planting, silkworm rearing and silk reeling and weaving. The integration of aquaculture and agriculture systems and silviculture is an old, widespread and enduring practice in south and south-east China. According to the literature, such systems existed in the Tang Dynasty (7th century AD), but did not flourish until the 14th century of the Yuan Dynasty. In the Zhujiang Delta ponds were dug to drain marshes and natural ponds in order to create arable land, and the excavated soil was used to construct dykes. The first commercial crops grown on the dykes were fruits, particularly litchi and longan, while the early artificial ponds were utilized for breeding and rearing fish for sale. However, there was apparently little or no conscious organization of an integrated fruit dyke–fishpond system in terms of linked input and output of material and energy, although both



Source: Agricultural Treatise of Wang Zheng

Figure 9.1 *The farming chart in Wang Zheng Nong Shu*

activities might be going on at the same farm unit. By 1620, however, mulberry was widely cultivated on the dykes between the fishponds. Experience has shown that economic returns from integrated mulberry dyke–fishpond systems were greater than those obtained from cultivating fruit trees on the dykes. Moreover, pond mud enriched with silkworm excrement and other wastes that had been first used to fertilize the pond and feed the fish was found to be a superior fertilizer for mulberry bushes than raw silkworm excrement which, when applied to excess, damaged mulberry leaves. With this discovery an integrated dyke–pond system was found to be beneficial to both mulberry and fish, and far better than growing rice.

Thoughts and practices in the Ming and Qing Dynasties

Nong Zheng Quan Shu (Complete Treatise on Agriculture), an unprecedented monumental work compiled by Xu Guangqi (1562–1633), an outstanding scientist of the Ming Dynasty (1368–1644), in mathematics and astronomy as well as use of the lunar calendar. This book contains more than 700,000 words and makes use of 229 written documents. It is the most comprehensive of all works on agriculture up to that time. The 60 volumes of the book are divided into 12 sections:

1 agriculture as the foundation (classics, history, literary references, various schools of thought, miscellaneous essays, studies of various dynasty's policies stressing agriculture);

2 farmland systems;
3 farming (management and administration, land reclamation, issuing almanacs for enforcement, divination of seasons);
4 water conservancy;
5 agricultural implements;
6 cultivation;
7 sericulture;
8 extension of sericulture;
9 planting (cash crops);
10 animal husbandry;
11 processing and construction;
12 protection against disaster.

Many advanced thoughts on ecological and successful technologies were introduced in this treatise, including presentation of the intercropping system. For example, the well-known Tangua system has been shown to be the earliest practice in formulation of agroforestry. In fact, similar practices had been implemented in China and were recorded in the literature at least 200 years earlier than those reported in Myanmar. A detailed description on planting crops is described in *Nong Zheng Quan Shu*. During the first few years of establishment of young stands of Chinese fir, cereal crops can be cultivated between the rows of trees. This tree/crop interplanting system can accelerate the growth of both tree and crops to make full use of space. Xu Guangqi also introduced the technology of making sheepfolds on the banks of fishponds and sweeping the manure on the bank into the pond to feed the fish.

In *Zhi Huang Quan Shu* (A Monograph on the Control of Locusts), written in the Qing Dynasty, an example of using ducks to control pests was given: in a mountain region, the locusts were caught by 700 ducks. Besides, raising ducks in paddy fields could also help to catch other leafhoppers.

The *Bu Nong Shu* (Additional Farming Book), written more than 300 years ago, stated that 'The manure of human and other animals as well as ash and dirt will become food and clothes soon if they are put into fields.' Farming, animal husbandry and composting were tightly combined in order to preserve biodiversity in the agriculture system. Crop stalks, manure of human and animals, organic wastes, etc. were put together to make compost, then applied into fields on the basis of 'come from soil, return to soil'. In this book an integrated system in the low wetlands of Zhejiang Province was described in which grain crops and mulberry trees were planted and fish and livestock were raised. By the end of the Qing Dynasty (1911), the Pearl River (Zhujiang) Delta had this kind of agroecosystem developed in some 66,700ha, and by 1925, at the peak of Guangdong silk production, 93,000ha of dykes were planted with mulberry. But a massive decline was soon to set in with the worldwide Great Depression.

The excellent techniques used in the planning of farm landscapes of traditional agriculture in China included information on tall and short crops, trailing and erect stem plants, deep- and shallow-rooted plants, sun-loving plants and shade resistance, early and lately maturing varieties. These characteristics were expanded to include all land resources within the organic combination of agriculture, forestry, animal husbandry, fishery and sideline production, together with comprehensive development and beneficial recycling systems. In the Qing Dynasty four methods of raising fish with different foods and living condition were combined in the same pond to maximize use of the water, to save on bait and to increase efficiency. The system, in which grass carp, silver carp, variegated carp and common carp were fed in the same waterbody to rationally utilize the water, save forage and increase benefits, is still used nowadays.

A large variety of aquaculture and agriculture interactive systems have been developed in China. Sugarcane has been cultivated on the dykes since the beginning of this [20th] century. Despite the widespread adoption of sugarcane cultivation, many former mulberry dykes were converted to vegetable production or paddy rice. Historically, although excavation of fishponds and dyke construction is considered to be the best way of transforming formerly economically marginal areas, subject to a range of natural disasters, until 1949 cropping patterns on the dykes were dictated by market prices rather than by ecological considerations.

In the *Wei Ya Wen Ji* (Collected Works of Wei Ya Wen) written in the Ming Dynasty, it was recorded that a variety of small crab lived in paddy field and fed on tender sprouts of rice. To control this little crab, the local farmers raised ducks in the paddy. As a result, ducks produced meat and eggs, the paddy fields were fertilized by the manure of ducks and the little crabs and insect pests were devoured by the fish.

During the Ming and Qing Dynasties, multiple cropping spread throughout north and south China. In the *Jiang Nan Cui Geng Ke Dao Biao* (The Situation of Rice in South China), Li Yanzhang summarized the growing of double-harvest rice on wheat stubble in the south of the Yangtze River, in which barley was harvested in the last ten days of March and the wheat was harvested in the first ten days of April. Seed soaking was done in the first ten days of March and on 30 March the rice seedlings germinated. After the harvest of wheat, the fields were fertilized, ploughed and raked and then rice seedlings were transplanted. In this way, three harvests in one year are realized. In Hunan Province, beans were planted after rice harvesting, and ripened in winter; then wheat was planted in the field and ripened in the next summer, followed by rice, etc.

Development of Modern IFS

Rapid development and upgrading of knowledge in IFS

Since the founding of the People's Republic of China in 1949, there has been a rapid growth in population and the economy, together with a decrease in arable land and a deterioration in the environment. However, IFS has been revived and developed on an ever-wider scale and upgraded on the basis of modern science. For example, some very interesting results have been obtained on energy flow and nutrient cycles of some systems and systems dynamics analysis and simulation have been initiated. At the same time, many experimental farms and field stations have been established. These are important bases for scientific research as well as important areas for demonstration and extension to vast areas.

A monograph entitled *Agroecological Engineering in China*, edited by Ma Shijun and Li Songhua (1987), provides a review of the concepts, history, principles, major types, methods of analysis and assessment, as well as perspectives of implementation of IFS in China. Many other publications have expounded the structure and benefits of specific types of IFS. Although interesting facts and encouraging results have confirmed the great potential and inherent advantages in this system, most of these publications remain descriptive and qualitative rather than analytical, quantitative studies. Nevertheless, a few interesting projects have emerged in which systematic, in-depth studies were carried out. For example, the rubber/tea intercropping system, widely practised in tropical regions, has been subjected to detailed studies by the Yunnan Institute of Ecology and the Reclamation Bureau of Hainan Province. The most popular and successful model, the *Paulownia* intercropping system, was studied by the Chinese Academy of Forestry Sciences and other local institutions. It is of particular value to mention the work of Zhong Gongfu and his colleagues who have studied the terrestrial/aquatic interactive system in the Zhujiang (Pearl River) Delta in Guangdong Province since the early 1950s and published *Integrated Agriculture/Aquaculture in South China* in 1988. This examined the historical development, agricultural and aquacultural components, energy flow, labour requirements and household economics of the system and is the first ever broad analysis of any such traditional integrated system (Ruddle and Zhong, 1988).

Many films and videos have been created to introduce integrated farming projects and specific technology useful in this system. In recent years, a number of national and international symposia/workshops have been organized by the Chinese Academy of Sciences, Ministry of Agriculture and the Ecological Society of China. All of these have provided a sound basis for further development of the integrated systems in China.

Improvement of production organization and agricultural policies

Policies play an important role in the development of IFS. Before 1987 the agricultural administrative system of China had assumed the familiar three-tier form of the People's Commune, Production Brigade and Production Team. Nevertheless, the household remained the smallest single unit of Chinese social organization and one in which the *de facto* use and management of privately owned resources, such as small homestead garden plots and domestic animals, was vested.

Since December 1978 the notion of a highly collectivized and egalitarian society has gradually been repudiated. China has moved towards the creation of a mixed, state-owned, marketing economy with rural reforms giving more flexibility to individual householders. This has led to decollectivization of many agricultural practices, transforming the status of the individual family to the basic rural economic unit from *de facto* to *de jure*.

As a consequence of these reforms, most areas in rural China now practise some form of responsibility system, with land and production contracted either to individual households or to the production team. Since 1981 the government has devoted much effort to stabilize the present ownership structure of hills and forests, allotting hillsides to peasants for their private use and setting up the forest production responsibility system throughout the country. Barren hills and flood plains owned by the collectives have been offered partly or entirely to peasants to be used privately in a way consistent with their desires and management ability. The trees and grass growing on lots belong to the landholders, who are entitled to manage their allotments on a long-term basis. Allotments can also be inherited, and young trees and half-mature trees on these may be exchanged for money. Trees of economic value, e.g. bamboo groves and shelterbelts owned by a collective, can be either contracted to specialized teams or groups or to households. The opening and development of free markets has encouraged farmers to produce diversified products. In addition, rural village industries have developed rapidly. Some 1.56 million 'township enterprises' have been established, employing around 70 million workers. These are capable of processing some agricultural products. All these reforms and policies not only are economically successful but also promote the enthusiasm of the farmers to develop a diversified IFS in China.

Support and incentives from the government

The support and incentives provided by the government are indispensable for the rapid development of IFS. Because the concept of ecoagriculture conforms to the basic strategy for development of agriculture, the Chinese Government attaches great importance to its development. In 1984, the State Council formally promulgated a decision on further expanding ecological agriculture in China. Soon after that the Eighth Five-Year National Development Plan decided to develop demonstration engineering for ecological agriculture. The requirement for conservation of national resources and development of ecoagriculture has been explicitly delineated in the Ninth Five-Year Plan for development of the national economy and society. The comprehensive management for sustainable agricultural development has been emphasized in China's Agenda 21, a significant national document for further domestic economic growth and medium- to long-term development and was approved by the State Council on 25 March 1994 in the form of the White Paper on China's Population, Environment and Development in the Twenty-first Century. Due to stimulation from government at various levels, ecoagriculture has been developed rapidly and profitably from household, to village, to county, as well as the regional level. In 1993, a leading group for the construction of eco-counties was approved by the State Council. This cross-ministry organization consists of representatives of the Ministry of Agriculture, the State Planning Commission, the National Environmental Protection Agency, the State Science and Technology Commission, the Ministry of Finance, the Ministry of Forestry and the Ministry of Water Resources.

The need for incentives to encourage farmers to adopt IFS practice, particularly the initial stages, is well recognized, as farmers do not have the resources to invest in reforming their conventional mono-cultivation system into a diversified integrated system. There are many forms of incentives in China; some direct and others indirect. Direct incentives include subsidies and loans to the farmers. Indirect incentives include technical assistance, tax exemption, tax deductions, security in land tenure, and marketing services. The goal of the incentive schemes is to encourage eventual self-reliance on the part of the farmer and the community and should fit in both short- and long-range plans.

By 1999, 51 counties contained trial sites for implementation of IFS. Although these sites are varied in scale as well as in physical and social conditions, most have obtained remarkable results. In 2000, another 100 counties were selected as trial sites. Therefore, China's IFS, or ecological agriculture, with a long history of development in ancient China, has been enriched and upgraded with the progress of modern science and technology, and has gradually become a real approach for sustainable agriculture.

Farmers of Forty Centuries

F. H. King

A word of introduction is needed to place the reader at the best viewpoint from which to consider what is said in the following pages regarding the agricultural practices and customs of China, Korea and Japan. It should be borne in mind that the great factors which today characterize, dominate and determine the agricultural and other industrial operations of Western nations were physical impossibilities to them 100 years ago, and until then had been so to all people.

It should be observed, too, that the US as yet is a nation of but few people widely scattered over a broad virgin land with more than 20 acres to the support of every man, woman and child, while the people whose practices are to be considered are toiling in fields tilled more than 3000 years and who have scarcely more than two acres per capita,[1] more than one-half of which is uncultivable mountain land.

Again, the great movement of cargoes of feeding stuffs and mineral fertilizers to western Europe and to the eastern US began less than a century ago and has never been possible as a means of maintaining soil fertility in China, Korea or Japan, nor can it be continued indefinitely in either Europe or America. These importations are for the time making tolerable the waste of plant food materials through our modern systems of sewage disposal and other faulty practices; but the Mongolian races have held all such wastes, both urban and rural, and many others which we ignore, sacred to agriculture, applying them to their fields.

We are to consider some of the practices of a virile race of some 500 millions of people who have an unimpaired inheritance moving with the momentum acquired through 4000 years; a people morally and intellectually strong, mechanically capable, who are awakening to a utilization of all the possibilities which science and invention during recent years have brought to Western nations; and a people who have long dearly loved peace but who can and will fight in self-defence if compelled to do so.

We had long desired to stand face to face with Chinese and Japanese farmers; to walk through their fields and to learn by seeing some of their methods, appliances and practices which centuries of stress and experience have led these oldest farmers in the world to adopt. We desired to learn how it is possible, after 20 and

Reprinted from King F H. 1911. *Farmers of Forty Centuries*, Rodale Press, Penn., pp1–13.

perhaps 30 or even 40 centuries, for their soils to be made to produce sufficiently for the maintenance of such dense populations as are living now in these three countries. We have now had this opportunity and almost every day we were instructed, surprised and amazed at the conditions and practices which confronted us whichever way we turned; instructed in the ways and extent to which these nations for centuries have been and are conserving and utilizing their natural resources, surprised at the magnitude of the returns they are getting from their fields, and amazed at the amount of efficient human labour cheerfully given for a daily wage of five cents and their food, or for 15 cents, US currency, without food.

The three main islands of Japan in 1907 had a population of 46,977,003 maintained on 20,000 square miles of cultivated field. This is at the rate of more than three people to each acre, and of 2349 to each square mile; and yet the total agricultural imports into Japan in 1907 exceeded the agricultural exports by less than one dollar per capita. If the cultivated land of Holland is estimated at but one-third of her total area, the density of her population in 1905 was, on this basis, less than one-third that of Japan in her three main islands. At the same time Japan is feeding 69 horses and 56 cattle, nearly all labouring animals, to each square mile of cultivated field, while we were feeding in 1900 but 30 horses and mules per same area, these being our labouring animals.

As coarse food transformers Japan was maintaining 16,500,000 domestic fowl, 825 per square mile, but only one for almost three of her people. We were maintaining, in 1900, 250,600,000 poultry, but only 387 per square mile of cultivated field and yet more than three for each person. Japan's coarse food transformers in the form of swine, goats and sheep aggregated but 13 to the square mile and provided but one of these units for each 180 of her people; while in the US in 1900 there were being maintained, as transformers of grass and coarse grain into meat and milk, 95 cattle, 99 sheep and 72 swine per each square mile of improved farms. In this reckoning each of the cattle should be counted as the equivalent of perhaps five of the sheep and swine, for the transforming power of the dairy cow is high. On this basis we are maintaining at the rate of more than 646 of the Japanese units per square mile, and more than five of these to every man, woman and child, instead of one to every 180 of the population, as is the case in Japan.

Correspondingly accurate statistics are not accessible for China but in the Shantung province we talked with a farmer having 12 in his family and who kept one donkey, one cow, both exclusively labouring animals, and two pigs on 2.5 acres of cultivated land where he grew wheat, millet, sweet potatoes and beans. Here is a density of population equal to 3072 people, 256 donkeys, 256 cattle and 512 swine per square mile. In another instance where the holding was one and two-thirds acres the farmer had 10 in his family and was maintaining one donkey and one pig, giving to this farm land a maintenance capacity of 3840 people, 384 donkeys and 384 pigs to the square mile, or 240 people, 24 donkeys and 24 pigs to one of our 40-acre farms which our farmers regard too small for a single family. The average of seven Chinese holdings which we visited and where we obtained similar data indicates a maintenance capacity for those lands of 1783 people, 212 cattle or donkeys and 399 swine – 1995 consumers and 399 rough food transformers per square mile of farm land. These statements for China represent strictly rural populations. The rural population of the US in 1900 was placed at the rate of 61 per square mile of improved farm land and there were 30 horses and mules. In Japan the rural population had a density in 1907 of 1922 per square mile, and of horses and cattle together 125.

The population of the large island of Chungming in the mouth of the Yangtse river, having an area of 270 square miles, possessed, according to the official census of 1902, a density of 3700 per square mile and yet there was but one large city on the island, hence the population is largely rural.

It could not be other than a matter of the highest industrial, educational and social importance to all nations if there might be brought to them a full and accurate account of all those conditions which have made it possible for such dense populations to be maintained so largely upon the products of Chinese, Korean and Japanese soils. Many of the steps, phases and practices through which this evolution has passed are irrevocably buried in the past but such remarkable maintenance efficiency attained centuries ago and projected into the present with little apparent decadence merits the most profound study and the time is fully ripe when it should be made. Living as we are in the morning of a century of transition from isolated to cosmopolitan national life when profound readjustments, industrial, educational and social, must result, such an investigation cannot be made too soon. It is high time for each nation to study the others and by mutual agreement and cooperative effort, the results of such studies should become available to all concerned, made so in the spirit that each should become coordinate and mutually helpful component factors in the world's progress.

One very appropriate and immensely helpful means for attacking this problem, and which should prove mutually helpful to citizen and state, would be for the higher educational institutions of all nations, instead of exchanging courtesies through their baseball teams, to send select bodies of their best students under competent leadership and by international agreement, both east and west, organizing therefrom investigating bodies each containing components of the Eastern and Western civilization and whose purpose it should be to study specifically set problems. Such a movement well conceived and directed, manned by the most capable young men, should create an international acquaintance and spread broadcast a body of important knowledge which would develop as the young men mature and contribute immensely toward world peace and world progress. If some broad plan of international effort such as is here suggested were organized the expense of maintenance might well be met by diverting so much as is needful from the large sums set aside for the expansion of navies, for such steps as these, taken in the interests of world uplift and world peace, could not fail to be more efficacious and less expensive than increase in fighting equipment. It would cultivate the spirit of pulling together and of a square deal rather than one of holding aloof and of striving to gain unneighbourly advantage.

Many factors and conditions conspire to give to the farms and farmers of the Far East their high maintenance efficiency and some of these may be succinctly stated. The portions of China, Korea and Japan where dense populations have developed and are being maintained occupy exceptionally favourable geographic positions so far as these influence agricultural production. Canton in the south of China has the latitude of Havana, Cuba, while Mukden in Manchuria, and northern Honshu in Japan are only as far north as New York city, Chicago and northern California. The US lies mainly between 50° and 30° of latitude while these three countries lie between 40° and 20°, some 700 miles further south. This difference of position, giving them longer seasons, has made it possible for them to devise systems of agriculture whereby they grow two, three and even four crops on the same piece of ground each year. In southern China, in Formosa and in parts of Japan two crops of rice are grown; in the Chekiang province there may be a crop of rape, of wheat or barley or of Windsor beans or clover which is followed in midsummer by another of cotton or of rice. In the Shantung province wheat or barley in the winter and spring may be followed in summer by large or small millet, sweet potatoes, soybeans or peanuts. At Tientsin, 39° north, in the latitude of Cincinnati, Indianapolis and Springfield, Illinois, we talked with a farmer who followed his crop of wheat on his smallholding with one of onions and the onions with cabbage, realizing from the three crops at the rate of $163, gold, per acre; and with another who planted Irish potatoes at the earliest opportunity in the spring, marketing them when small, and following these with radishes, the radishes with cabbage, realizing from the three crops at the rate of $203 per acre.

Nearly 500,000,000 people are being maintained, chiefly upon the products of an area smaller than the improved farm lands of the US. Complete a square on the lines drawn from Chicago southward to the Gulf and westward across Kansas, and there will be enclosed an area greater than the cultivated fields of China, Korea and Japan and from which five times our present population are fed.

The rainfall in these countries is not only larger than that even in our Atlantic and Gulf states, but it falls more exclusively during the summer season when its efficiency in crop production may be highest. South China has a rainfall of some 80 inches with little of it during the winter, while in our southern states the rainfall is nearer 60 inches with less than one-half of it between June and September. Along a line drawn from Lake Superior through central Texas the yearly precipitation is about 30 inches but only 16 inches of this falls during the months May to September; while in the Shantung province, China, with an annual rainfall of little more than 24 inches, 17 of these fall during the months designated and most of this in July and August. When it is stated that under the best tillage and with no loss of water through percolation, most of our agricultural crops require 300 to 600 tons of water for each ton of dry substance brought to maturity, it can be readily understood that the right amount of available moisture, coming at the proper time, must be one of the prime factors of a high maintenance capacity for any soil, and hence that in the Far East, with their intensive methods, it is possible to make their soils yield large returns.

The selection of rice and of the millets as the great staple food crops of these three nations, and the systems of agriculture they have evolved to realize the most from them, are to us remarkable and indicate a grasp of essentials and principles which may well cause Western nations to pause and reflect.

Notwithstanding the large and favourable rainfall of these countries, each of the nations have selected the one crop which permits them to utilize not only practically the entire amount of rain which falls upon their fields, but in addition enormous volumes of the run-off from adjacent uncultivable mountain country. Wherever paddy fields are practicable there rice is grown. In the three main islands of Japan 56 per cent of the cultivated fields, 11,000 square miles, is laid out for rice growing and is maintained under water from transplanting to near harvest time, after which the land is allowed to dry, to be devoted to dry land crops during the balance of the year, where the season permits.

To anyone who studies the agricultural methods of the Far East in the field it is evident that these people, centuries ago, came to appreciate the value of water in crop production as no other nations have. They have adapted conditions to crops and crops to conditions until with rice they have a cereal which permits the most intense fertilization and at the same time the ensuring of maximum yields against both drought and flood. With the practice of Western nations in all humid climates, no matter how completely and highly we fertilize, in more years than not yields are reduced by a deficiency or an excess of water.

It is difficult to convey, by word or map, an adequate conception of the magnitude of the systems of canalization which contribute primarily to rice culture. A conservative estimate would place the miles of canals in China at fully 200,000 and there are probably more miles of canal in China, Korea and Japan than there are miles of railroad in the US. China alone has as many acres in rice each year as the US has in wheat and her annual product is more than double and probably threefold our annual wheat crop, and yet the whole of the rice area produces at least one and sometimes two other crops each year.

The selection of the quick-maturing, drought-resisting millets as the great staple food crops to be grown wherever water is not available for irrigation, and the almost universal planting in hills or drills, permitting intertillage, thus adopting centuries ago the utilization of earth mulches in conserving soil moisture, has enabled these people to secure maximum returns in seasons of drought and where the rainfall is small. The millets thrive in the hot summer climates; they survive when the available soil moisture is reduced to a low limit, and they grow vigorously when the heavy rains come. Thus we find in the Far East, with more rainfall and a better distribution of it than occurs in the US, and with warmer, longer seasons, that these people have with rare wisdom combined both irrigation and dry farming methods to an extent and with an intensity far beyond anything our people have ever dreamed, in order that they might maintain their dense populations.

Notwithstanding the fact that in each of these countries the soils are naturally more than ordinarily deep, inherently fertile and enduring, judicious and rational methods of fertilization are everywhere practised; but not until recent years, and only in Japan, have mineral commercial fertilizers been used. For centuries, however, all cultivated lands, including adjacent hill and mountain sides, the canals, streams and the sea have been made to contribute what they could toward the fertilization of cultivated fields and these contributions in the aggregate have been large. In China, in Korea and in Japan all but the inaccessible portions of their vast extent of mountain and hill lands have long been taxed to their full capacity for fuel, lumber and herbage for green manure and compost material; and the ash of practically all of the fuel and of all of the lumber used at home finds its way ultimately to the fields as fertilizer.

In China enormous quantities of canal mud are applied to the fields, sometimes at the rate of even 70 and more tons per acre. So, too, where there are no canals, both soil and subsoil are carried into the villages and there between the intervals when needed they are, at the expense of great labour, composted with organic refuse and often afterwards dried and pulverized before being carried back and used on the fields as home-made fertilizers. Manure of all kinds, human and animal, is religiously saved and applied to the fields in a manner which secures an efficiency far above our own practices. Statistics obtained through the Bureau of Agriculture, Japan, place the amount of human waste in that country in 1908 at 23,950,295 tons, or 1.75 tons per acre of her cultivated land. The International Concession of the city of Shanghai, in 1908, sold to a Chinese contractor the privilege of entering residences and public places early in the morning of each day in the year and removing the night soil, receiving therefore more than $31,000, gold, for 78,000 tons of waste. All of this we not only throw away but expend much larger sums in doing so.

Japan's production of fertilizing material, regularly prepared and applied to the land annually, amounts to more than 4.5 tons per acre of cultivated field exclusive of the commercial fertilizers purchased. Between Shanhaikwan and Mukden in Manchuria we passed, on 18 June, thousands of tons of the dry highly nitrified compost soil recently carried into the fields and laid down in piles where it was waiting to be 'fed to the crops'.

It was not until 1888, and then after a prolonged war of more than 30 years, generalled by the best scientists of all Europe, that it was finally conceded as demonstrated that leguminous plants acting as hosts for lower organisms living on their roots are largely responsible for the maintenance of soil nitrogen, drawing it directly from the air to which it is returned through the processes of decay. But centuries of practice had taught the Far East farmers that the culture and use of these crops are essential to enduring fertility, and so in each of the three countries the growing of legumes in rotation with other crops vary extensively for the express purpose of fertilizing the soil is one of their old, fixed practices.

Just before, or immediately after the rice crop is harvested, fields are often sowed to 'clover' (*Astragalus sinicus*) which is allowed to grow until near the next transplanting time when it is either turned under directly, or more often stacked along the canals and saturated while doing so with soft mud dipped from the bottom of the canal. After fermenting 20 or 30 days it is applied to the field. And so it is literally true that these old world farmers whom we regard as ignorant, perhaps because they do not ride sulky ploughs as we do, have long included legumes in their crop rotation, regarding them as indispensable.

Time is a function of every life process as it is of every physical, chemical and mental reaction. The husbandman is an industrial biologist and as such is compelled to shape his operations so as to conform with the time requirements of his crops. The oriental farmer is a time economizer beyond all others. He utilizes the first and last minute and all that are between. The foreigner accuses the Chinaman of being always long on time, never in a fret, never in a hurry. This is quite true and made possible for the reason that they are a people who definitely set their faces towards the future and lead time by the forelock. They have long realized that much time is required to transform organic matter into forms available for plant food and although they are the heaviest users in the world, the largest portion of this organic matter is predigested with soil or subsoil before it is applied to their fields, and at an enormous cost of human time and labour, but it practically lengthens their growing season and enables them to adopt a system of multiple cropping which would not otherwise be possible. By planting in hills and rows with intertillage it is very common to see three crops growing upon the same field at one time, but in different stages of maturity, one nearly ready to harvest; one just coming up, and the other at the stage when it is drawing most heavily upon the soil. By such practice, with heavy fertilization, and by supplemental irrigation when needful, the soil is made to do full duty throughout the growing season.

Then, notwithstanding the enormous acreage of rice planted each year in these countries, it is all set in hills and every spear is transplanted. Doing this, they save in many ways except in the matter of human labour, which is the one thing they have in excess. By thoroughly preparing the seed bed, fertilizing highly and giving the most careful attention, they are able to grow on one acre, during 30 to 50 days, enough plants to occupy ten acres and in the mean time on the other nine acres crops are maturing, being harvested and the fields being fitted to receive the rice when it is ready for transplanting, and in effect this interval of time is added to their growing season.

Silk culture is a great and, in some ways, one of the most remarkable industries of the Orient. Remarkable for its magnitude; for having had its birthplace apparently in oldest China at least 2700 years BC; for having been laid on the domestication of a wild insect of the woods; and for having lived through more than 4000 years, expanding until a million-dollar cargo of the product has been laid down on our western coast and rushed by special fast express to the east for the Christmas trade.

A low estimate of China's production of raw silk would be 120,000,000 pounds annually, and this with the output of Japan, Korea and a small area of southern Manchuria, would probably exceed 150,000,000 pounds annually, representing a total value of perhaps $700,000,000, quite equalling in value the wheat crop of the US, but produced on less than one-eighth the area of our wheat fields.

The cultivation of tea in China and Japan is another of the great industries of these nations, taking rank with that of sericulture if not above it in the important part it plays in the welfare of the people. There is little reason to doubt that this industry has its foundation in the need of something to render boiled water palatable for drinking purposes. The drinking of boiled water is universally adopted in these countries as an individually available and thoroughly efficient safeguard against that class of deadly disease germs which thus far it has been impossible to exclude from the drinking water of any densely peopled country.

Judged by the success of the most thorough sanitary measures thus far instituted, and taking into consideration the inherent difficulties which must increase enormously with increasing populations, it appears inevitable that modern methods must ultimately fail in sanitary efficiency and that absolute safety can be secured only in some manner having the equivalent effect of boiling drinking water, long ago adopted by the Mongolian races.

In the year 1907 Japan had 124,482 acres of land in tea plantations, producing 60,877,975 pounds of cured tea. In China the volume annually produced is much larger than that of Japan, 40,000,000 pounds going annually to Tibet alone from the Szechwan province; and the direct export to foreign countries was, in 1905, 176,027,255 pounds, and in 1906 it was 180,271,000, so that their annual export must exceed 200,000,000 pounds with a total annual output more than double this amount of cured tea.

But above any other factor, and perhaps greater than all of them combined in contributing to the high maintenance efficiency attained in these countries, must be placed the standard of living to which the industrial classes have been compelled to adjust themselves, combined with their remarkable industry and with the most intense economy they practise along every line of effort and of living.

Almost every foot of land is made to contribute material for food, fuel or fabric. Everything which can be made edible serves as food for man or domestic animals. Whatever cannot be eaten or worn is used for fuel. The wastes of the body, of fuel and of fabric worn beyond other use are taken back to the field; before doing so they are housed against waste from weather, compounded with intelligence and forethought and patiently laboured with through one, three or even six months, to bring them into the most efficient form to serve as manure for the soil or as feed for the crop. It seems to be a golden rule with these industrial classes, or if not golden, then an inviolable one, that whenever an extra hour or day of labour can promise even a little larger return then that shall be given, and neither a rainy day nor the hottest sunshine shall be permitted to cancel the obligation or defer its execution.

Note

1 This figure was wrongly stated in the first edition as 1 acre, owing to a mistake in confusing the area of cultivated land with total area.

Part III

Agricultural Revolutions and Change

11

Agricultural Sustainability and Open-Field Farming in England, c. 1650–1830

Michael Turner, John Beckett and Bethanie Afton

Introduction

Sustainability has become a key concept in the modern approach to development studies. The guiding definition proposed in 1987 by the World Commission on Environment and Development (Brundtland Commission) emphasized that 'Sustainable development is that development that meets the needs of the present generation without compromising the ability of future generations to meet their own needs' (World Commission, 1987, p144). To that extent sustainability was regarded as something to be achieved in the future, which can in turn lead to a view of the past in which everything had been sustainable, but this was a state of affairs that had only recently changed or was in danger of changing. Thus Conway and Pretty (1991, p1) invoke a distant past (or certainly the pre-1945 period), in heralding the problems of the present or very recent past in agricultural development:

> … agriculture, for most of its history, has been environmentally benign. Even when industrial technology began to have an impact in the eighteenth and nineteenth centuries, agriculture continued to rely on natural ecological processes. Crop residues were incorporated into the soil or fed to livestock, and the manure returned to the land in amounts that could be absorbed and utilised. The traditional mixed farm was a closed, stable and sustainable ecological system, generating few external impacts. Since the Second World War this system had disintegrated. (Conway and Pretty, 1991, p1)

This suggests that there are lessons for the future that might be drawn from the past. In this sense Pretty's (1991) summary of extension practices in the classical British 'Agricultural Revolution' demonstrated the way the past has sometimes prefigured the future.

Reprinted from Turner M, Beckett J and Afton B. 2003. Agricultural sustainability and open-field farming in England, c. 1650–1830. *Int J Agric Sust* 1(2), pp124–140, Earthscan.

Nevertheless, the late 20th-century agricultural revolution in industrialized countries suggests a quantum leap in modern agricultural change. Thus Wes Jackson (1980, pp2–3) pointed to the enormity of the process of post-1945 change: 'So destructive has the agricultural revolution been that, geologically speaking, it surely stands as the most significant and explosive event to appear on the face of the earth…' Yet there is no doubt that in the past there was real ecological stress caused by farming practised in particular contexts. All societies have had to adapt to forces over which they have had little or no control (Mannion, 1995, pp83–84; Evans, 1998, pp57–61). By looking at some specific historical features in the context of the modern debate over sustainability, we may be able to offer some new perspectives on agriculture. The purpose of this paper is to examine the issue of agricultural sustainability specifically in the historical context of open-field farming in the English midland counties. While there is a tradition in agrarian history to address some of the issues that we raise in the paper, we do not think that a concerted attempt has been made to place agricultural or indeed rural history into the holistic framework that we explore here. Standard historical assessments of the past did not have the benefits of modern thinking on sustainability, yet all of them contain elements that might be reconfigured in its language (Tawney, 1912; Hoskins, 1949b; Broad, 1980; Butlin, 1982; Havinden, 1961).

But we believe that this could be a two-way street. While our fellow historians might benefit from the language of the present we wonder whether present environmental concerns about soil, and more widely, resource degradation, and the solutions offered, might reflect that these concerns had been confronted in the past in England. Many local solutions were found by trial and error in the English open fields that in modern parlance (see Wendell Berry's Foreword in Jackson, 1996) might be termed resource management schemes.

The Geographical and Chronological Context

Our focus of attention in this paper is specific. We concentrate on the open-field farming system that prevailed over much of England until its final dissolution in the 80 or so years after 1750. This was a system that was based on communally administered agricultural organization and production, and it persisted, sometimes without any major adjustments, for several centuries. It was part of the northern European system of communal agriculture, though most historians would recognize significant regional variations even within the confines of the British Isles (Baker and Butlin, 1973). The study of the system has relatively recently undergone renewed attention under the gaze of New Institutional Economics. This relates to collective action and land rights, by which route it has modern applications in quite diverse societies and contexts (see for example Hardin, 1968; Ostrom, 1990; Baland and Platteau, 1998). While open-field farming in communally organized ways prevailed to a greater or lesser degree over nearly all of England, it was most prevalent and survived longest in a narrower geographical region. This was particularly concentrated in the midland counties of England. We therefore draw our main references from Bedfordshire, Buckinghamshire, Leicestershire, Lincolnshire, Northamptonshire, Nottinghamshire and Rutland, forming a contiguous group of counties in the central and eastern parts of England (though we also include some references to adjacent counties).

An impression of the prevalence and persistence of open-field farming is best demonstrated by measuring its dissolution. There are various ways by which this was achieved, all of which fall under the description of enclosure, but the fullest record of enclosure was undertaken through private and local acts of parliament, most of which changed the farming system from communal to several (private) ownership, and from communal to several administration. This was achieved mainly on a village by village basis (Turner, 1984). Figure 11.1 locates our study area, but in representing the incidence of enclosure in a quantified way it also measures the size of the task that was undertaken, and thereby conveys the importance of the process in the whole history of English agricultural change. The mirror image of enclosure is precisely the dominance of open-field farming. The illustrative village examples we subsequently use demonstrate some of the pressures that open-field farming faced and how they were resisted. However, these pressures were eventually too great to resist the final outcome, which was the ultimate dissolution of the open-field farming system by enclosure.

The Simplified Model

The standard literature of traditional agricultural history has still properly to acknowledge modern methodologies of approach. The core elements of agricultural sustainability that we adopt here first came to our attention through relatively little-known work (Pannell and Schilizzi, 1999), which encouraged a wider review of the literature (to include Norman et al, 1997; Pretty, 2002; Uphoff, 2002; O'Riordan and Stoll-Kleemann, 2003). The core model appropriate to a lengthy historical dimension embraces ecology, economy and equity. The last in this list is our adaptation of what might equally be referred to as ethics. The appropriateness of this adaptation should become apparent as these three elements in the model are applied to our empirical base. In the best of sustainable worlds they should be in harmony. It is when these linkages separated that we conclude that farming in a sustainability framework was at risk.

The principal *ecological* elements of our application of sustainability relate to husbandry practices, and the extent to which these maximized the use of the available land resources without compromising soil quality, soil texture and underlying fertility. This was achieved by using a nutrient recycling regime. However, it must be understood that this took place during a time of relative scientific ignorance, and therefore it was recognized by contemporaries through time-honoured processes. These included the use of tried and tested crop rotations, including experimentation with plants capable of fixing atmospheric nitrogen, even if this scientific

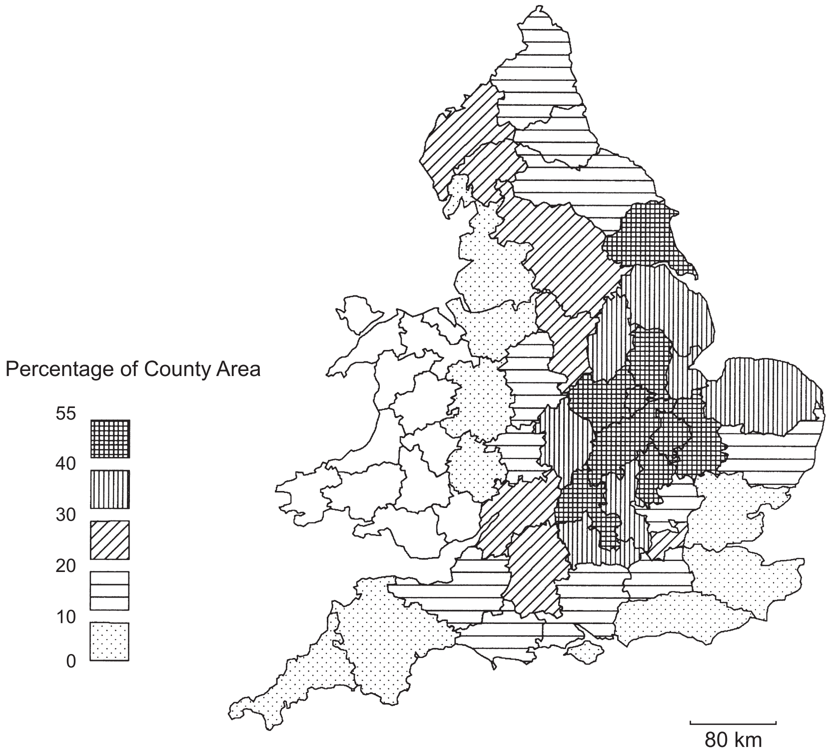

Figure 11.1 *Density of parliamentary enclosure, c. 1740–1840 (England only)*

process was not understood at the time. The end result was the crop, but measured through yields or by the deterioration or improvement in those yields according to the laboratory of experience over the generations. By such methods, for example, medieval farmers in Oxfordshire solved the problem of nitrogen management (Newman and Harvey, 1997). Ecological considerations also involved application of animal manures, and thus returning the nutrients otherwise removed by farming. We take this as a given in modern society, but in the past it came about by experiment and experience. The integration of plants and animals was essential, and in a world of limited resources recycling evolved as the antidote to resource loss. In the words of Sir Albert Howard in 1940 there was an ecological balance in which:

> Mother earth never attempts to farm without livestock; she always raises mixed crops; great pains are taken to preserve the soil and prevent erosion; the mixed vegetable and animal wastes are converted into humus; there is no waste; the processes of growth and the processes of decay balance one another; ample provision is made to maintain large reserves of fertility; the greatest care is taken to store the rainfall; both plants and animals are left to protect themselves from disease. (quoted by Jackson in Soule and Piper, 1992, pxiv)

Successions of farmers mimicked nature but they did this by a process of chance and folk experience rather than by the grand designs that are available in modern agriculture.

The second core element was *economy*, which is recognized as a critical issue in modern literature (Heap, 1992; Gregorich, 1995; Pannell and Schilizzi, 1999). Self-evidently no system is sustainable if farmers go out of business, but the rural community also maintained many other groups and individuals, including landlords, through traditional landlord/tenant relationships, and armies of service providers. The English village evolved as a community of responsible, self-regulating partners, with a duty not simply to the present but also to future generations. Obviously the potential legacy had to be tempered by current need, including a direct income to each generation of farmers. To this extent our characterization of the village community may seem idealized, but periodically the community was subject to risks of shortage and sometimes the ultimate penalty when poor harvests had ensuing mortality consequences. The troughs of hardship were broken up by long periods of, not necessarily plenty, but a less romanticized sufficiency which made communities think about their long-term survival strategies. There have been well-defined periods in English history when the ultimate calamity in agricultural supply resulted in deepest famine and mortality crises, but in the period on which we concentrate, the link between food shortage as measured by adjustments in the relationship of crop and food prices and mortality is statistically weak (Wrigley and Schofield, 1981, pp371–372). We contend that this was because the management of resources, and thus the sustainability of the agricultural system, was successful not least because of the strengths of the communal organization of agriculture. To this extent we are certain that our understanding does not fall foul of a romantic view of the past that tends 'to presume that "tradition" is somehow "good" for ecosystem maintenance' (O'Riordan, 2003, p8). If communal decision making, very often based on tradition, is still very much a feature of non-Western agriculture, then perhaps therein lies a strength rather than a weakness which can be built upon (to this extent many of the modern-day examples in Uphoff, 2002, are built on a tradition of community ownership and participation).

The third core element is *equity*. Farmers were the stewards of the environment they inhabited. In their contemporary language they were judged on whether they cared for the land in a *husbandlike* manner, or with a care for the well-being of the farming habitat. This has always implied ensuring that the soil would retain its fertility. In practice this involved farming in a manner agreed to be the best practice in the locality. However, not all farmers behaved in the same way and with the same attitude of care. Moreover, the resource that delivered the product – the soil itself – was communally administered and subject to a good deal of communal sharing. Therefore good husbandry must not always be assumed, it might have been enforced – through lease covenants for example. Nevertheless, the reward was *equitably* derived in that all participants shared in both the ownership and/or the management of local resources. Disputes over equitable access to these resources were the most common ways in which sustainable agriculture was compromised, hence an elaborate system of manorial and other local courts acted as regulators and policemen within the community. Access to the outcome of farming, to the food itself, also had to be equitable. As in modern societies, so also in the past, there was a basic requirement for secure and adequate food. To that extent we can invoke Sen's modern theory of entitlements. This he related to famines in which supply was not the problem, rather it was the equity of access to that supply that was put at risk. So also in the English open-field village basic output was also adequate but in time there developed a problem over the equity of access to that output (Sen, 1981, 1986).

The Experience of Open-Field England

The textbook management system of the English open fields suggests they operated in a rotational process involving three fields. This simple characterization hides the flexibility and variation within the system. In a study of the organization of Leicestershire church property in the 17th century, Beresford (1949) found that 9 per cent of the parishes for which he had information were more simply arranged in two rather than three fields, 79 per cent were in three, and the remainder in combinations of four, five and more fields. In 18th-century Northamptonshire 57 villages were in four or more fields (Hall, 1995, pp157–164), and although the Nottinghamshire village of Laxton, which incidentally is the last unenclosed example of open-field husbandry to survive on any scale, was a four-field village it was worked on a three-course rotation (Beckett, 1989, pp43–45). Generally in the midland counties each field was divided into a multitude of other units known variously as furlongs, strips and lands, not all of which would necessarily be under the same land use as their neighbours at any one time. For example, at Husbands Bosworth in Leicestershire in 1770, the North Field was divided into 109 arable strips, 56 under temporary grass leys, and 46 in more or less permanent meadow. In the South Field there were 105 strips of arable and 67 in leys, and in West Field there were 102 in arable and 74 in leys (Beresford, 1949). Such divisions within fields made more complex cropping patterns possible, but if we simplify things we recognize three basic 'units' of rotation, the corn crops, the pulses and the fallow. The corn 'unit' was typically sown to barley, wheat or rye (Leicestershire Archives, DE 783/78; Northamptonshire Archives, IL 16).

For much of the early part of the period barley was the most common crop. In Leicestershire, between 1558 and 1608, the acreage of barley averaged between 35 and 40 per cent of the cropped arable. Wheat varied between 8.5 and 14 per cent and rye declined from 8.5 per cent to an insignificant amount by the early 17th century (Hoskins, 1950, pp168, 171; Thirsk, 1954, p212). Barley had the advantage of flexibility in its end use because it could be used for bread and beer production, and also as animal feed, and its straw made fodder and other products.

The flexibility of the open-field system was maximized by having alternative grain crops. For example, wheat and rye were autumn-sown crops, while barley was planted in the spring. Sometimes such flexibility was paramount where the vagaries of the weather in relation to the underlying soil structure demanded it. On the extensive clayland for example, inadequate drainage resulted in excessive water retention and this meant that the period during which the ground could be prepared for cropping was limited. In such circumstances, when there was a delay in the preparation of the ground, the ability to plant a spring-sown crop was not just desirable, it was vital to the general well-being of the community. Yet in some parishes otherwise dominated by the heavy clays, there were also areas where quite different soils also existed. Here the planting of rye provided a good alternative because it could be concentrated in those parts of the open fields least likely to produce good crops of wheat or barley. In such cases it was grown every second or third year (Hoskins, 1950, pp163–165). The inclusion of similar crops that provided such flexibility in response to soil conditions, the weather and the market, went a long way to ensuring the ecological sustainability of the open fields.

In time the growth of the market economy saw adjustments in the grain crop mix, in particular there was a shift towards wheat, which became the premier cash crop. In 32 open-field villages in Bedfordshire in 1801 31 per cent of the arable was under wheat, and 18 per cent under barley. In neighbouring Northamptonshire the equivalent distribution was 31 per cent wheat and 27 per cent barley (Turner, 1989, p52). In comparable Leicestershire villages wheat was planted on between 27 and 30 per cent of the cropped arable in the three open fields, while barley occupied between 18 and 25 per cent (Hoskins, 1949a, pp134–135). Rye remained as the dominant bread grain in much of north and east Europe but by the period under review it was only occasionally planted in England, and then mixed with wheat as a bread grain known regionally as muncorn, maslin, blend corn and other names. By the late 18th century whenever it was grown, however rarely, it was used mainly as an early spring feed crop rather than as a bread grain (Hoskins, 1949b, pp161, 174). By 1801 only 3 per cent of the open fields of Bedfordshire were sown with rye, and less than 1 per cent of those in Northamptonshire (Turner, 1989, p52). Nevertheless, what we can conclude of the bread grains is that within communally administered agricultural systems there was adaptability that had evolved over many generations.

The second part of the rotation was generically known as the pease field (whether it was one or more actual fields), and represented the pulse rotation. Traditionally, beans and peas were planted in the late winter. The land was ploughed typically at Epiphany (6 January), left for a short while so that frost action could break it up further, and then sown. The purpose of this course was mainly as livestock feed. In Leicestershire in the second half of the 16th century, peas (the term was used indiscriminately for both peas and beans) commonly occupied 35–40 per cent of the cropped arable (Hoskins, 1950, pp168, 171; Thirsk, 1954, p212). By 1801 we know that 47 per cent or so of the cropped arable in the Leicestershire villages of Congerstone, Glenfield and Bringhurst was under beans or peas (Hoskins, 1949a, pp134–135), though in the county as a whole the proportion was only 9 per cent. By 1801 much of this county had been enclosed and converted to pasture (Turner, 1981, p296). The balance in other places was quite different: in Bedfordshire 21 per cent of the arable in 32 open-field parishes was under peas and beans, and 29 per cent in 45 Northamptonshire parishes (Turner, 1989, p52).

While pulses are less efficient at fixing atmospheric nitrogen than are small seeded legumes such as clover, trefoil or sainfoin, they would have made at least as important a contribution to the amount of nitrogen in the system thereby helping to ensure the overall sustainability of the arable (Shiel, 1991, p76). The standard model of the nitrogen cycle suggests that grain crops can experience an increase in yields of 15 kilograms for every one kilogram of nitrogen supplied, but this relationship does not expand infinitely. Instead it is driven by Liebig's 'Law of the Minimum' in which the initial nitrogen deficiency is rectified by the fixing of nitrogen from appropriate crops in a more or less linear relationship of 1:15 until such time that a limit is achieved. Beyond this limit further application of nitrogen does not result in further yield improvements. Thus the integral base fertility of the soil was maintained but constantly we need to remind ourselves that this was not scientifically understood. Instead it was a sustainability cycle borne of generations of experience and experimentation. So what might appear as cutting edge innovation in crop mixes was more likely to have evolved through trial and error. For example, oats were occasionally planted in the pease field (Marshall, 1790, p225), but if they were this took place in late spring, and in common with the use of barley in the corn field, they provided a safety net if bad weather had previously prevented farmers from sowing pulses. This safety net ensured sustenance for the animals. The pease or pulse course might occupy as much as 50 per cent of the arable land that was not in fallow, and its principal purpose was to supply fodder for the livestock.

The final course in the rotation was the fallow, which was a restorative period, without the demands of a sown crop. It also acted as a cleaning period, providing an opportunity to remove weeds from the field. Once the pease crop was harvested the field was thrown open for livestock to feed on the stubble, on remnant grasses, weeds and the grass leys. Depasturing also took place on the passageways that afforded access into and across the fields. These were strips of lands known as baulks and headlands. They were integral to the fields and their functions. So also, paradoxically, were weeds. If they were allowed to proliferate at certain times this was not always a sign of backwardness in field management. Arthur Young, the noted agricultural writer and traveller of the late 18th and early 19th centuries observed, 'you cannot clear weeds until first you let them germinate' (Young, 1771, p291). Therefore the fallow field was not normally ploughed in the autumn. Instead the weed seeds were allowed to germinate, thus providing feed for the sheep that were grazed on the fallow. The first ploughing was left until late in the spring (Marshall, 1790, p225; Loudon, 1831, p802; Fox, 1981, pp94–95). A second ploughing was typically made in midsummer, when any weeds which were going to seed were ploughed in before they produced seed heads. A final ploughing occurred about the autumn equinox, shortly before the autumn sowing of the succeeding corn crop. Consequently through the fallow year the field was cleared of sufficient weeds to minimize competition for the limited nutrients available for the future cultivated crops. The groundcover provided by the weeds limited the leaching of nutrients and the erosion of the topsoil. It helped to recycle the nitrogen fixed while the field was in pease. At the same time the field was rested from the demands of a cropping routine, and provided an important source of feed for the sheep, according to the local rules regarding stinting, which in turn provided dung. Thus a neat cycle of nutrient renewal took place year upon year.

The open-field system had evolved in such a way as to be ecologically sustainable. The throughput of crops in the different rotations created a biologically diverse system and the pease field compensated for any shortages of permanent grass, or any tendency to acquire more land under cereal according to temporal economic circumstances. The system minimized losses by maintaining ground cover, and by using a variety of plants it kept nutrients within the system. Recycling, through the actions of the sheep and their digestive system and their natural tendency to tread in their waste, along with the ploughing in of anything left uneaten by the animals, also helped with biodiversity. The principle of farming in nature's image was practised, and the successful integration of plants and animals helped to ensure that the system remained viable across the centuries.

The impact of domestic forces

Seemingly therefore the open-field system was in harmony with sustainable ecological principles while allowing for changes in emphasis at the margin that did not upset the whole system. However, it did not operate in a vacuum. Economic considerations and challenges to equity or fairness had the power to disrupt this ecological balance. In particular there was the impact of large-scale changes in society in general of which the individual villages formed a microcosm. For example, changes in population had an impact on prices and the relative benefits of concentrating on bread foods or the more varied diets offered by a mix of bread and animal products. Yet it was possible for the flexibility of the open-field system to react to such population pressures without initially disrupting what we have described as a sustainable farming system based on open-field management.

From around 5.2 million in c. 1650, the population of England declined to about 4.9 million in 1681, and recovered only slowly to reach 5.8 million by 1751. Only in one half decade from 1681 to 1751 did numbers rise by more than 0.5 per cent per annum and in two half decades the population actually fell (1681–1686 and 1726–1731). On the downturn or during times of relatively stable population the result was cheaper bread for consumers, but farmers found that their incomes were squeezed, especially as corn bounties designed to encourage the export of the grain surplus had only a marginal effect in propping up prices. Grain prices fell steadily from a base of 100 in 1650 to 68 in the mid 1740s with obvious implications for the level of farmers' incomes. As we shall see later, they reacted by

Table 11.1 *Agricultural product price indexes for the main 'Cash Crops' 1650–1812*

Date	*Wheat*	*Butter*	*Milk*	*Beef*	*Mutton*
1650	100	100	100	100	100
1745	68	102	112	103	83
1765	103 (100)	111 (100)	119 (100)	119 (100)	102 (100)
1790	119 (116)	121 (109)	171 (144)	156 (131)	126 (124)
1806	205 (199)	196 (177)	277 (233)	275 (231)	211 (207)
1812	222 (216)	227 (205)	359 (302)	281 (236)	222 (218)

Note: 11-year moving averages, rebased on 1650. Apart from the base in 1650 the years selected are determined by the price of wheat at the maxima, minima, the landmark price when the base price was restored, and when the 200 index barrier was broken. (The index has been rebased in 1765 to show the subsequent relative inflation of prices from the new base.)

Source: Adapted from Clark, 2004

attempting to adjust the ecological balance between grain and animal production. From the mid-18th century population began to rise and prices in turn recovered to the original base 100 by 1765, and then advanced to 119 by 1790. After 1750 the growth of population was uninterrupted and provided some boost to demand and the resulting recovery of prices shown in Table 11.1. In 1751 the population was 5.8 million, and by 1771 it was 6.4 million. By the 1790s it had grown to 7.7 million (in 1791) and on to 8.7 million by 1801 (Schofield, 1994, p64). The conjunction of this population change with the outbreak of war in 1793, a war that lasted more or less continuously until 1815, meant that prices took off, reaching an index on our scale of 200 by 1805 and a high point of 222 by 1812.

This conjunction of demographic and economic circumstances forced agriculturalists to respond by adjusting the ways they worked the land, yet ideally without upsetting the ecological balance or compromising equitable access to resources. The compliance of the landlords and their stewards in this role was also important as witness their abatement of rents during times of economic distress (Turner et al, 1997, *passim*). But there were other ways of adjustment. The balance between arable and pasture or meadow varied between areas and between parishes, and altering this balance was a task for the community. At Withern with Woodthorpe in Lincolnshire, this task is recorded in the Field Reeves Book. It is a record of the annual decisions made about local farming (Lincolnshire Archives, Misc Dep 199/1). In March 1792 it was agreed that the occupiers would seed and stint, that is apportion the use of the fields, as agreed by the majority. The administrators of these decisions and rules (the field reeves) were an elected body and it was up to them to order and direct the management of local drainage, the care of the fields, and the regulation of the numbers of stock that were allowed to graze on the fields at designated times of the year. For example, in November 1799 they agreed to sow the stubble field with corn the 'insuing year owing to the unfavourable state of the fallows in the other field from the excessive wetness of the season'. This was a season by season communal management that was adjusted to accommodate fluctuating annual conditions. In other places such adjustments became permanent features. For example, at Heath and Reach in Bedfordshire it was decided that the traditional three-field system could only be improved by fallowing every fourth year instead of every three. Therefore in 1814 the system of two crops and a fallow became three crops and a fallow in which the third crop was clover, or what others might see as a cropped fallow. It was also agreed that anyone wishing to sow turnip seed or potatoes in the fallow field could do so (Bedfordshire Archives, BO/1334). In Oxfordshire, the open fields were often broken up into larger numbers of rotational units to get around the rigidities of operating only in a two- or three-field manner. At Kirtlington this adaptability reached new heights when 12 arable divisions replaced the original two fields (Lambert, 1955). Such adjustments helped to maintain the ecological integrity of the soil as well as demonstrating equity of ownership through equity of decision making.

We know that in some areas it was possible to modify and adapt the open-field systems to accommodate new crops and new rotations (the examples above and generally in Havinden, 1961). However, such open-field flexibility was by no means certain, and there is no satisfactory way of quantifying the production or consumption of the numerous new crops which were thus cultivated, nor whether they were always first introduced into the open-field system (Thirsk, 1997). For example, both woad and rapeseed (to name only two examples) seem generally to have been grown in areas of old enclosure outside the common fields. In the case of woad, in the Midlands generally but notably in Northamptonshire, it is not clear whether it was introduced into the open fields, rather than the woodland areas. Many parishes also had areas of enclosed land, usually under grass but sometimes in exhausting arable crops such as hemp, flax or hops (Mingay, 1984, p96). Economic considerations forced communities not only to consider new crops but also whether to alter the ratio of arable to grass. During the demographic quietus before 1750, and in the light of the stable or declining crop price profile it encountered and partly determined, there was a countervailing history of higher prices for meat and dairy products, as well as a rising industrial demand for wool and other raw materials derived from agriculture. The conjunction of these factors encouraged a move away from arable production towards grass (Jones, 1967, p8). With relatively stable contemporary wages in association with the decline in basic bread prices (as depicted in the wheat price trend in Table 11.1), the implied increase in purchasing power was spent by switching demand to animals and animal products, the prices of which held up throughout the period (Table 11.1). Grain prices recovered in the third and fourth quarters of the 18th century in response to the early effects of the demographic revolution which we date to this period. Yet adjustments in standards of living which we associate with the richer society that developed and which defied the Malthusian spectre, meant that dietary changes that were already in place could flourish. To that extent there was no reversal of the trend that was in place. In Table 11.1, in parenthesis, we rework the price trend to show that the terms of trade may have turned back towards grain but not sufficiently to dampen the enthusiasm for livestock products, the prices for which held up. The terms of trade between arable and pastoral products (wheat relative to butter, milk, beef and mutton in Table 11.1) did not move against pastoral products by 1790 (except butter), nor by 1806 and 1812 (again except for butter). Scholars' interpretations of the price inflation of this, the French wars period, had been mixed until Hueckel (1976) constructed a series of terms of trade indexes between arable and pastoral products. These more or less confirm the surge of demand for pastoral products that we also identify and to which we return below.

Transformations responding to domestic forces

Adjustments in the land use mix were not always in the gift of individuals in communally shared resources such as encountered in open-field agriculture. Instead, local courts of administration, the manor courts, circumscribed by ancient manorial procedures, still operated in the 18th century. According to Tate such control of the open fields and associated commons was never formally transferred from the manor and its courts to other local courts, though an act of 1773 devolved powers to manage the common fields to a three quarters majority in favour of the landowners. There are examples below which post-date 1773 and which suggest that the ceding of power away from the manorial courts was not everywhere recognized (Tate, 1969, pp258–267). Yet regardless of such niceties, it remained the case that the community in some shape or form had to decide on changes it wished to implement, and to accept the risks involved. If, for example, it agreed to abandon all or part of the mixed farming of the common fields in favour of permanent pasture, it had also to recognize the consequences on the ecological balance, the economic rewards, and the equity of resource use.

Agricultural communities across the Midlands responded to the economic considerations of the period post-1650 by a series of improvements. We are talking here about constant annual management rather than revolutionary change – changes that were 'unambitious and quite small in scale'. These consisted of the regulation of commons, partial enclosures, consolidation of scattered holdings, intakes of waste, and conversion of old arable land to grass and the breaking-up and improvement of ancient pastures (Mingay, 1984, p122).

The first adjustment within the open fields involved creating new grass or preserving existing grass resources. In the demographic conditions before the third quarter of the 18th century, with the economic or market attractiveness of pastoral products relative to grain products, there was mounting pressure put on grazing resources. This led to overgrazing of stock, which threatened to degrade the communal resources, the commons and the cow pastures. In compensation, parcels of land were laid down in temporary grass leys. Such convertible husbandry was already well established by the 16th century and by the 17th century the division of fields into arable and ley or grass-ground had become common (Beresford, 1949, p92; Hunt, 1957, p270; Hall, 1995, pp20–29, 157–164). It involved intermixing grass leys with the cropped lands or strips in the open fields. On farms owned by New College Oxford in Hempton in 1624, 24 per cent of the land was in grass leys, in Addlesbury in 1628 it was 16 per cent, and in Shutford in 1653 it was 34 per cent (Havinden, 1961, p74). Pasture shortages by the end of the 17th century led the commoners at Ibstock to convert two lands to grass leys for every yardland held in the Neather Field, specifically to augment the cow pasture (Leicestershire Archives, DE 390/56. A yardland was an old method of describing and crudely measuring an area of land but it varied in precise size even from parish to parish let alone from one county or broad district to another. A rule of thumb suggests that a yardland was about 30 acres or 12 hectares). At Grafton in Northamptonshire in the 1720s and 1730s it was proposed that no more than one-third of the land in the common fields should be under the plough and the rest in grass (Northamptonshire Archives, G3883). At Lubenham in Leicestershire in 1734 four tenants renting from Samuel Wright had on average 36 per cent of their open-field land in grass leys rather than arable crops (Leicestershire Archives, DE 2960).

One of the advantages of laying parcels of land down in temporary grass leys is that it improves biodiversity and helps to integrate livestock and crops in a balanced, ecologically sustainable manner. We say this not as a post-Brundtland analytical rationalization of an ancient system, but rather as a recognition that historians have clearly identified a custom and practice in operation that can now be presented in modern terms. Moreover, it stands in contrast to other agricultural systems which were more land abundant than England. We have in mind here the kind of settlement history in 19th-century North America where settlers moved on to new ground once they had exhausted the old ground since that was automatically a way of recovering biodiversity lost through soil exhaustion. In the meantime the exhausted ground took 20 or more years to recover through natural regenerative means. There was a limit to the extent to which such practices could prevail, a limit that was reached many generations ago in England. Instead convertible husbandry became the solution.

The second means of adjusting the terms of trade between crops and animals was through piecemeal enclosure of small areas of the open fields, usually in the period under study and for the geography we have identified, for conversion to permanent pasture. Typically this occurred at the edges of parishes remote from the core of arable activity, on land which because of its location may have been starved of manure and the very best husbandlike attention. These old enclosures ranged from bite-sized pieces to very extensive but mostly contiguous stretches of land (Thomas, 1933, p79; Swales, 1937, p245; Turner, 1980, pp137–141; Hall, 1995, p22). Many of these intakes from the communal lands probably began as arable ley grounds located at the fringes of the open fields or in reasonably compact blocks that did not interfere with the general farming of the arable field (Hoskins, 1957, pp160–164). Whatever their origin, these enclosures came to be managed outside the open-field system. At Hallaton, Leicestershire, in 1707, 36 per cent or 796 acres (322 hectares) of the village was enclosed in this fashion leaving the remainder open (Leicestershire Archives, DE 339/340). Out of 932 acres

(377 hectares) surveyed at Lubenham in 1734, 75 per cent was enclosed (Leicestershire Archives, DE 2960). At Laxton in Nottinghamshire from 1894 acres (767 hectares) which were once open fields, 1143 acres (463 hectares or 60 per cent) were still open in 1736 (Beckett, 1989, p317). Occasionally individual fields were removed from cultivation altogether. At Cotgrave in Nottinghamshire one of the four open fields was turned down to grass in 1717, and the others followed piecemeal until the enclosure legislation of the 1790s simply confirmed that the village was now almost entirely in pasture (Nottingham University Manuscripts Department, MaB). At Orston, also in Nottinghamshire, both in 1730 and in 1753 and piecemeal thereafter, there was conversion to permanent grass from the open-field arable to such an extent that by 1793 only 14 per cent remained in arable. This soon disappeared following the enclosure of that year (Barnes, 1997, pp125–132).

A third method that altered the balance of arable and grass was the enforcement or revision of agreements that restricted grazing rights. The owners of cottages and holdings had rights to graze a given number and type of animal on the commons, and on the crop stubbles after harvest. Permanent commons were usually on poor ground or waste, but that made it even more important that the correct stocking density was maintained with a mixture of types, ages and sexes of animal, to maximize the maintenance of a good grass sward. Though contemporaries were aware that grassland would benefit from careful management, nevertheless commons were often seriously neglected, and even encroached upon. In an attempt to control the situation at Cosgrove in Northamptonshire, the field orders of 1686 required that 'all those persons that have flocke or flockes upon the green or any other part of the commons or waste shall take them off by the first of February next' (Northamptonshire Archives, FS70/1). In Leicestershire, the Sheppy Magna manor court in the late 18th and early 19th century disallowed repeated encroachments on the communal wasteland, opened them up and returned them to communal use (Leicestershire Archives, DE 798/1; Turner, 1980, p143). Once the rules were enforced and unauthorized encroachments ended, the equitable access to agrarian resources was restored.

The enforcement of stinting agreements and field orders helped to maintain the integrity of the open-field farming system. New and revised agreements bemoaned the neglect and over-stocking that occurred by way of justifying amendments or the enforcement of new stints. Penalties were imposed for failure to comply with the rules, thus restating the importance attached to communal equity in the use of these common resources. Exceeding the agreed stints was effectively the theft of an inequitable share of the forage. At Wigston Magna in Leicestershire in 1707 after a number of disputes over rights to common grazing, it was agreed to reduce the cattle stint from eight to four beasts and the sheep stint from 40 to 24 (Hoskins, 1957, pp238–240). At Castle Donington, also in Leicestershire, grazing resources were in such short supply that in 1737 they were eaten off by early summer. In consequence the cow pasture stint was reduced by 25 per cent and the sheep stint by 50 per cent (Leicestershire Archives, DG8/24). The necessity of imposing stints was expressed by the preamble to their renewal in 1718 at Little Bowden in Northamptonshire, when both the cattle and sheep stints were reduced by a half (Northamptonshire Archives, TLB/84).

Such rules protected the common grazing on both the commons and the arable stubbles, but the frequency of their renewal is suggestive of the pressure to increase animal stocks. At Orston in Northamptonshire the manor court determined the stint annually (Barnes, 1997), and a similar task fell to the field reeve at Withern with Woodthorpe in Lincolnshire (Lincolnshire Archives, 199/1). In an attempt to keep track of the cattle in Billington in Bedfordshire each commoner was required to notify the teller in writing by the end of March of the number of cattle he was keeping on the common. This broke down in 1772 when it was found that '… the Commons and Commonable Fields … have been overcharged and burdened with too many cattle to the great injury and prejudice … etc'. In consequence the stint was reduced (Bedfordshire Archives, BO1326).

Many agreements specifically prohibited the use of the commons by anyone without grazing rights, a reminder that modern-day ideas regarding commons developed out of specific and relatively narrow land rights. The commoners at Cosgrove in Northamptonshire agreed in 1715 only to rent spare stints on the common land to fellow Cosgrove villagers and not to outsiders (Northamptonshire Archives, YZ7849). At Gilmorton in Leicestershire in 1722 the agreements stipulated that 'No one shall lett sell give or dispose of his sheep commons from the Feast of St Martin until Ladyday [to persons] not living in Gilmorton but can receive compensation of 1 1/2 d for every sheep common not stocked or stored if notice is given to the constable…' (Leicestershire Archives, DE66). This is akin to a public good where the definition of 'public' is more like what Pretty and Ward refer to in a modern setting as a 'club' good (Pretty and Ward, 2001, pp210, 221 note 2).

Two equity principles were most abused and thereby tested by stinting regulations and other field orders. The first was the time-honoured egalitarian principle that individuals should not keep more stock on the commons in the summer than they could reasonably feed on their own land in winter. Thus at Ibstock in Leicestershire in 1696 it was agreed that 'Field masters shall yearly once betwixt Lady Day and midsummer and once between midsummer and Michaelmas drive the fields and take an exact account of every mans stock that no person keep any more cattle than he have commons for in the common fields or pasture' (Leicestershire Archives, D E 390/56). The second was a clarification of the ownership and stewardship of common community resources. The common cause of tensions was the overstocking of the commons in the face of market pressures (widely discussed in Ault, 1954; Yelling, 1977, pp153–156; Turner, 1980, pp145–149). For the community to regulate itself in the face of such pressures, the local manorial and other courts had to be active, but their powers were gradually eroded more or less by the difficulty of policing the common property. Each time a parcel of land was removed from the communally administered system, everyone else's entitlement was adversely affected. The more this occurred the more occasions the local courts had to intervene, but also the more often their powers were questioned and sometimes ignored. In consequence the local court system collapsed or was forced to accede to local pressures, often because farmers were searching for ways to respond to everyday market forces. The courts were simply not equipped to counter the demand for economic individuality, which could often be achieved only through the formal and legal procedure of enclosure. Barnes has shown how the erosion of power exercised by local courts unfolded in the Nottinghamshire village of Orston (Barnes, 1997).

The Final Breakdown

We have stressed the capacity of open-field communities to react to pressures, whether of an ecological, economic or equitable nature, by adjusting farming and yet retaining sustainability. Yet in the longer term the open-field system collapsed. As a system it was, in modern terminology, unsustainable. It was possible to adjust the ecological balance, to lay down areas of arable to grass, to enclose areas of remote arable for permanent pasture, or to alter the stints on the commons, but the degree to which the system was completely flexible and therefore inviolable is open to question. The local ecology may have been firmly established but the system of managing it could not resist external economic considerations, particularly in the form of agricultural commercialization in the face of changing demand. Ultimately something more fundamental was needed, and this was to be enclosure and the parcellation of land into individual properties. At the same time it meant the extinction of common rights. At Wendover in Buckinghamshire in 1777 an act was secured to exchange land in the open fields to create a degree of consolidation of otherwise intermixed land ownership. This was not a full enclosure but rather a consolidation, but it did require the break-up of boundaries and access points between ownership strips and therefore the loss of scattered sheep pastures, since those boundary and access lands were usually grassed over. One of the local courts agreed to let clover and turnips be sown in place of the lost pasture. This arrangement proceeded smoothly for 12 years until one of the farmers turned a flock of sheep onto the clover in May before the agreed time for depasturing. The crop was lost, equity was challenged, and the parishioners proceeded to a formal enclosure through a parliamentary act (James and Malcolm, 1794, p29). This and countless examples like it, and also the variations of it that we have intimated, existed in the 17th and 18th centuries and are real-life examples of Hardin's theoretical 'tragedy of the commons' in which individual and collective utility are sometimes at odds with each other (Hardin, 1968, p1240).

In its purest form the open-field system was non-specialized and non-intensive. It was developed in a context of relative community self-sufficiency (which underpinned ecological, economic and equitable considerations). In saying this we recognize that the village was never entirely self-sufficient because taxes and rents left the community, market goods were bought in, and there were also significant commodity trades, for example in seeds. Nevertheless, it was fundamentally unsuited to and therefore unsustainable in the context of a market economy which emphasized the virtues of regional and local specialization. This is what emerged from the economic conditions of the century or so after 1650 and which in the midland counties of England tended to suit livestock farming and its end products ranging from meat and wool to milk. On the heavy clays of the English midlands the production of turnips, which was increasingly transforming light soil areas such as Norfolk, was inappropriate. In contrast, the increasingly developing exchange economy, which was underpinned by river navigation improvements, canals and turnpike roads, suggested the virtues of increased specialization which in the study area pointed to the advantages of a grass-based agricultural economy. From the 17th century, and probably even earlier in some parts, the pressure built up sufficiently to suggest that the adaptations to the system we have described were inadequate. Enclosure and the ending of common property rights in favour of separate and individual ownership became the order of the day. A rising tide of opinion from the 17th century onwards and culminating in Arthur Young's invective against open-field agriculture and the 'Goths and Vandals' who managed them in the 1760s and 1770s convincingly championed the benefits of farming in severalty (entirely private farming) (Mingay, 1975, p99). While the potential costs deterred (or at least deferred) enclosure, in the end market forces could not easily be resisted whatever the potential threat to the rural community (Mingay, 1984, pp96, 117).

In the light of the price trends we have discussed, pastoral farming made economic sense in the period leading up to the mid-18th century, especially on the heavy clays of the study area, the English midland counties. The pressure to convert to pasture inevitably increased the pressure to enclose (Turner, 1980, ch 6). Ecological issues also intruded, particularly the management of animals. Breed management could improve the productivity of a flock or herd by matching breed and use – for example by developing specialized cattle breeds for dairying, or by using early maturing animals in a feeding/fatting system. But communal grazing was a barrier to the improvement of livestock through selective breeding. In addition, disease control became increasingly important as the value of the stock increased, but this was difficult to undertake with communal grazing. We are uncertain of the extent to which communal regulations of stock density of the sort that we have already discussed were on their own sufficient to maintain the quality of stock, though we also have spasmodic indications of specific regulations that were introduced. For example, regulations were put in place at Mountsorrell in Leicestershire, specifically banning sheep with scab and infectious cattle from grazing on the commons (Leicestershire Archives, DE 40/46/3). Within the old system, any change in animal husbandry relied on the efforts of the entire community, including those with little interest in the new ways. Individuals had insufficient daily control of their animals to maintain standards that were relatively easy to achieve on enclosed farms. A system reliant on communal action was no longer sustainable. The shift towards specialized and more productive and intensive agriculture was outside the scope of a system originally established and developed to provide the needs of a largely self-sufficient community. It was not sustainable at the higher levels of productivity that could be reached by farming in severalty. The three principles in the sustainability model – ecology, economy and equity – sometimes pulled in opposing directions.

Farming in severalty facilitated changes of the sort that open-field agriculture could only introduce slowly and in piecemeal fashion. It was as if the remedies we have discussed above were remedial – meeting crises as and when – rather than inclusive of the changes in population and demand that required more decisive action. That decisive action became enclosure. The open fields were abandoned, not all at a rush, but over a long period, with definable peaks of activity. Our earlier discussion of the study area of contiguous counties indicates both the location and the intensity of enclosure, but it hides the fact that this enclosure took place in two waves of activity. There was a first intensive enclosure in the third quarter of the 18th century in which the trends towards more pastoral activity detectable for 100 years or so was intensified. There was then a lull in activity in the 1780s before a resurgence of enclosure in the 1790s and on to 1815 and a slowdown thereafter. Thus the dismantling of the open fields had been in full flow up to the 1780s and how long the system would have taken to disappear entirely we shall never know, because the whole process took a new turn in 1793 when Britain entered into what turned out to be more than 20 years of (almost) uninterrupted conflict with France.

Inevitably, for an island state, the first and most pressing question to arise concerned the security and adequacy of food supplies. This quest tended to compromise environmental stewardship and equitable access to resources. In the 1790s a conjunction of circumstances including bad harvests and the impact of the war produced an inflation of prices (Table 11.1) and this exposed the vulnerability of the national economy. In the years 1771–1793 inclusive, the price of wheat rose above 50 shillings per quarter in only 7 years, and at its worst reached 54.75 shillings in 1790. (There were eight bushels in a quarter, and a bushel weighs some 25kg.) In four other years it was at or below 40 shillings per quarter. It averaged 46.6 shillings per quarter from 1771 to 1789. But from 1794 to 1821 it was always above 50 shillings. In the 1790s it was 57.6 shillings, but for the whole duration of the war it averaged 80.6 shillings per quarter. At its wartime peak the price of wheat stood at 126.5 shillings per quarter in 1812, falling to 65 shillings in 1815 and 44 shillings in 1822. It was not until 1835 that the price of wheat reduced to a level (at 39 shillings per quarter) comparable to the level of the distant generation of the early 1760s (Mitchell and Deane, 1962, pp487–488; Clark, 2004). But this was not just an inflation of grain prices, because as Table 11.1 indicates the inflation was just as strong for animal-derived products. The conjunction of war and demography was very potent on price trends but the enclosures and agricultural improvements that ensued were complicated.

In these circumstances the long-term movement we have described towards converting arable land to grassland at first sight seems to fall foul of the new contemporary contrary pressures to raise arable output during the wartime conflict. Enclosures on the heavy clays of the midland counties continued to feed the desire for more animal products, perhaps not to the same degree as prevailed in earlier decades, but nonetheless the trend was not reversed. Instead, during the war the grain crises for a country now under siege were relieved by enclosure of a different sort. There was the enclosure of the lighter soils, of the sort that occurred on the East Yorkshire and Lincolnshire Wolds, which could benefit in a different way from farming in severalty – not for conversion to pasture but for intensification of the arable (Turner, 1984, pp16–23). There was also a reclamation of otherwise ill-used land, the commons and upland sheep walks, moors and mosses, all commonly called at the time 'wasteland'. There may not have been a plough-up campaign to rival the ones witnessed in 1916–1918 or 1939–1944, but there was certainly a good deal of Parliamentary rhetoric along such lines. In 1803 Sir John Sinclair, a Scottish MP and President of the Board of Agriculture, called for an attack on the commons and wastes, and not just the highland ones. 'Let us not be satisfied with the liberation of Egypt, or the subjugation of Malta, but let us subdue Finchley Common; let us conquer Hounslow Heath, let us compel Epping Forest to submit to the yoke of improvement' (Turner, 1984, p23). This was intervention by default, but clearly the message suggested that the ecological balance might need to be compromised for the wider equitable crisis, not in this case of the community, but of government and the nation state itself. Sir John and the champions of enclosure could not be sure of the long-term impact of enclosing land that was otherwise used for traditional moorland or commons economy. It may not have compared with the ecological damage imparted by the wartime plough-up of sheep walks in the 20th century, but whether they recognized it or not, contemporaries threatened ecological sustainability by their short-term actions. They can have had few ideas as to the potential long-term damage they were in danger of imposing by enclosing commons and waste and then ploughing them for grain, but in the French wars, as in the 20th-century world wars, sustainability was compromised for reasons of national security.

Contemporary estimates suggest that the wheat acreage could have grown from something less than 2 million acres (0.8 million hectares) in the 1790s, to about 2.4 million acres (0.97 million ha) in 1801, and to 3.2 million acres (1.3 million ha) in 1808 (Turner, 1981, pp299–301). We cannot rely too heavily on these figures as they were based on little more than informed guesses, but they point towards a rapid complement to the trend towards grass, which had not been stemmed by the growth of population and grain prices from the 1760s. Furthermore, with spiralling prices as an incentive the old principles of equity were easily abandoned. Almost invariably enclosure began by extinguishing common rights, a gesture which symbolized the move away from the communal and towards the individual. The local communal administration with its policy of upholding common rights, by-laws, stints and other restrictions was swept away on this tide of individuality. Once lines of engagement had been drawn to divide the property and adjudicate on property rights, it meant the end of the communal care. At times enclosure was as much about the clarification of those property rights as it was about productivity strategies.

Enclosure, whether for extending the grassland or for improving the arable, represented the end of the old order. It brought with it the self-contained, ring-fenced farm, which in turn posed a new threat to sustainability. While the community with its local courts controlled farming practice, it also held back the enterprise of the individual. Through the enclosure process itself local legal restrictions operated by the enclosure commissioners ensured that all farmers were fairly treated (Beckett et al, 1998), but after enclosure those same farmers came directly under the control of landlords. At that juncture between community control and landlord control there was in some places and at some times a breathing space in which the accumulated sustainable work of decades or even centuries was put severely at risk. This was no better summed up than by Thomas Davis, a noted contemporary observer of the interface between communal open-field farming and farming in severalty. He said that enclosures made a good farmer better, but a bad farmer worse (Davis, 1811, p46). He meant that the good farmers were already resource managers but within a communal straitjacket, in contrast to the potentially indolent or inefficient farmers who were protected from doing great damage by the collective action embodied in communal management. Left to their own devices, once collective action was removed at enclosure, these farmers lost the plot and their part of the farming environment suffered. Therefore for future agricultural sustainability it was vital that the responsibilities undertaken by the local courts were transferred to the landlord, or more pertinently to his land agent. It is probably not coincidental that the late 18th and early 19th centuries witnessed growing professionalization of estate management. This was symbolized by the emergence of the land agent who replaced the old manorial steward, who had often been a lawyer employed mainly to oversee the operation of the manorial court (Beckett, 1986, p144). All the while there is also the age-old debate over the damage done to a landless sector of society when access to common resources was taken away by this enclosure process (Pretty, 2002, pp29–32).

Summary and Conclusion – Transitions in English Agrarian History

If Brundtland is the key definition of sustainability then open-field farming appeared to meet the needs of succeeding generations without compromising those of future generations. It was ecologically balanced, the economic benefits maintained the rural community, and it provided a degree of equitable access to resources. At the same time it was susceptible to adjustment, allowing communities to alter the balance between arable and pasture to reflect the wider economic world. Changing demand conditions constantly impinged on the three-attribute model of ecology, economy and equity, but inbuilt elasticity allowed temporary and also some permanent adjustments to be made without unbalancing the whole system. But that could not go on forever. The nature of demand developed throughout society with a rise of commercialization in manufacturing, a greater circulation of money, an extension of markets, and a greater variation in the demand for food away from mere survival needs to something more varied. This encouraged agricultural specialization, placed severe strains on traditional open-field agriculture, induced questions and decisions about land use and land access on a big enough scale to threaten the conditions of equity in the community, as well as putting the ecological balance of resources at risk. The resulting removal of collective responsibility at enclosure shifted the burden for sustainability from the community to the individual.

Sustainability is always threatened by crises, and sometimes short-term compromises are necessary. But in the longer term contemporaries understood and acted on the basis that agriculture must be sustainable. They may not have used the same terminology, but they understood that farming had to meet the needs of any particular generation without compromising the ability of future rural generations to meet their own needs. This is not some pie in the sky romantic view of the past but a realistic and honest assessment of the workings of the rural village economy. When they looked to make changes they did so cautiously, ensuring at each stage that the economic demands on farming did not compromise the ecological and equity considerations too much. Only under the stress of war were such considerations shuffled to one side. There are surely echoes of the traditional collective rural village economy in modern approaches to biodiversity, sustainability and communities (a play on words deliberately employed from the title of O'Riordan and Stoll-Kleemann, 2003 and further elaborated by O'Riordan in his introduction and partial summary of subsequent chapters, especially pp16–26).

Three hundred years ago in England the organization of the open fields more or less ensured that resources were used in a manner which was self-evidently good for the wider environment and community. This has also been illustrated in analyses that have a modern contemporary agenda as well as a historical focus (Skipp, 1978; Pearce et al, 1989; Soule and Piper, 1992; Pretty, 1995; MAFF, 1998). Moreover, the language of collective action has been employed recently to illustrate in other countries and in recent times how equitable solutions in rural communities have met the needs of local development in a sustainable fashion (Pretty and Ward, 2001; and many of the examples in Uphoff, 2002). Our point is that the history of open-field farming in England, and no doubt also in much of western and northern Europe, probably provides a laboratory of similar experiences from which modern analysts might derive some well-developed but perhaps now forgotten solutions. In this context it should not stretch the imagination to suggest that there are lessons to be gained from this passage of history to apply to the recent past, or indeed for application to present and future societies. Communal and quasi 'public good' resources can be managed even against the mounting odds posed by demographic and other internal and external pressures (such as war) that impinge upon them. The New Institutional Economics approach to common or corporate ownership has opened up new avenues of investigation of those circumstances that have determined the development from common to private forms of ownership and governance (Ostrom, 1990; Baland et al, 1998; Radkau, 2003). What we have offered here is an empirical example of that development but in the context of the modern theory of sustainable resource management.

Acknowledgements

We are grateful to the Economic and Social Research Council for their financial support of this project, the long-term intention of which is to offer a framework for examining the experience of farmers over the past 500 years within the context of the sustainability debate. We also thank Professor Greg Clark for the opportunity to use his price indexes ahead of publication. Finally we thank the anonymous referees who encouraged us to rework our ideas into a wider framework.

Farmers' Extension Practice and Technology Adaptation: Agricultural Revolution in 17th–19th-Century Britain[1]

Jules Pretty

Introduction

In the late 20th century agriculture faces enormous challenges. Production in industrial and green revolution agriculture is now close to or above levels that can be sustained by the natural resource base. Yet the demand for food and non-food products will grow as populations expand, so further increasing the pressure on natural resources. Agriculture expands into hitherto uncultivated forests, grasslands and wetlands; degrades on-farm resources through erosive and environmentally damaging practices; and transfers some of the costs of production off the farm to other sectors of the environment and economy (Barbier, 1989; Pretty, 1990a; Conway and Pretty, 1991).

The prospects would appear to be bleak. The growing food requirements will have to be met, at least in part, through improvements to agriculture in the resource-poor regions of the world. But farming households in these regions have poor access to external resources in the form of credit and nutrient and pest control inputs, are poorly served by rural roads and other infrastructure, and are rarely adequately supported by research and extension services. Where extension does reach them, the approach has been to attempt the transfer of technologies proven to work on research stations rather than on farmers' fields. New technologies rarely spread beyond the large farmers, and the aggregate impact remains small (Mullen, 1989; Russell et al, 1989; Pretty, 1990b).

However, in recent years increasing numbers of agricultural development schemes or projects have demonstrated that agricultural production can be improved in resource-poor regions through the adoption of technologies that maximize the use

of on farm resources provided that farming households themselves are fully involved in the generation of technologies, in their extension to other farmers, and in the experimental adaptation to local conditions (Jintrawet et al, 1985; Farrington and Martin, 1987; Chambers et al, 1989; Fujisaka, 1989; Bunch, 1990; Pretty, 1990b). In many locations, small revolutions in institutional support and farming practice are occurring. Returns to investment are rapid; the poor become better off and more secure; the region produces surpluses; and the country as a whole benefits.

Components of a revolution

Such a technical and biological revolution also occurred in rural Britain during the 17th to 19th centuries. During a period in which there was no government ministry of agriculture, no national agricultural research or extension institutions, no radio or television, no pesticides or inorganic fertilizers, and poor rural transport infrastructure, aggregate cereal and livestock production increased to unprecedented levels. In the 150 years after 1700, wheat production grew four fold, and barley and oats three fold; the numbers of cattle supplied to markets tripled and sheep doubled (Chartres, 1985; Holderness, 1989; Mingay, 1989; Beckett, 1990). This remarkable achievement was brought about in two ways: the extension, largely by farmers, of new technologies that intensified on-farm resource use; and the promotion of extensification by the conversion of common pastures and woodlands to private farming.

New crops offered diversified opportunities to farmers by allowing intensified use of land. Increased fodder supply meant more livestock and so increased supply of manures improved soil fertility. Selective breeding of livestock produced more efficient converters of feed to meat, so permitting slaughter at an earlier age and higher stocking rates. New labour-saving machinery released farmers from the labour-bottlenecks at cereal and hay harvests; and new tools and techniques improved the efficiency of seed sowing. Underfield drainage increased cropping options on marginal land; and irrigation of watermeadows increased the supply of fodder, particularly during the late winter shortage. Complementarities with urban and industrial growth – the British population tripled between 1700 and 1850 – also meant increased soil fertility as agriculture assimilated industrial and human wastes.

Coupled with this intensification were the dual enclosing processes of open-field conversion to private farming, and the enclosure of common property natural resources to produce more private farm land. Whether the former had an impact upon agricultural output is controversial; the latter, through the passing of more than 3500 Bills in Parliament, increased aggregate output as more than 650,000 hectares of woods, pastures, marshes and fens between 1730 and 1820 were enclosed (Jones, 1967). Both intensification and extensification resulted in a net benefit to the economy through growth in agricultural production – both yields per hectare and area under cereals roughly doubled between 1700 and 1850 (Turner, 1982, 1984; Overton, 1984a; Allen and O'Grada, 1988; Holderness, 1989; Beckett, 1990). But the costs attendant upon the two strategies differed. Intensification mostly used on-farm resources, absorbed industrial wastes, and did not damage the environment; extensification harmed the livelihoods of poor households by removing their rights and access to the common property resources on which they so heavily relied.

Views of innovation and adoption

Until the last two decades, orthodoxy has held that the British agricultural revolution began about 1760 and ended in the early 1800s (Ernle, 1912). Credit for progress was given to a few, now famous, innovators: Tull for his corn drill, Townshend for turnips, Coke for the Norfolk Four Course rotation, Bakewell for livestock breeding, and Young for promoting all of these. The conventional view is that, once exposed to these innovations, the majority of farmers adopted them and the revolution occurred. However, claims for innovation rapidly driving production growth have not survived scrutiny. Some have suggested that all improvements began by the 1580s, spread rapidly in the 1600s, and were completed by 1767 (Kerridge, 1967); whilst others suspect there was no major discontinuity, and that gradual change occurred throughout a period beginning at about 1600 and lasting to the 1840s, when further rapid change occurred as a result of increased use of external inputs (Overton 1984b; Thirsk, 1987).

What is now clear is that Tull, Townshend, Coke, Bakewell and Young were simply good popularizers rather than innovators. All 'their' innovations were being practised by some farmers 50–100 years before they were born (Table 12.1). The lasting fascination for 'inventors' has diverted attention away from the process of diffusion and adoption, and it remains to this day a heresy to many agricultural scientists to suggest that farmers have much to say in the process of technology generation, diffusion and adaptation (see Rhoades, 1989). Yet in the British agricultural revolution they were centrally involved in all three. Farmers made diffusion active rather

Table 12.1 *The first known dates of innovative technologies and techniques and the later popularizers associated with them*

Innovation	*First known*	*Popularizers and their lifespan*
Seed Drill	1600	Jethro Tull (1674–1741)
Turnips	Late 1500s	Charles 'Turnip' Townsend (1674–1738); Arthur Young (1741–1820)
Artifical 'Grasses' (including clovers, sainfoin, trefoil, lucerne, rye grass, rib grass, *etc*.)	1620–1640	Thomas Coke (1754–1842); Townshend; Young
Norfolk Four Course Rotation	late 1600s	Coke; Young
Selective Breeding of Livestock	late 1600s–1700s	Robert Bakewell (1725–1795)
Irrigated Watermeadows	late 1500s	Bakewell; Young

Sources: Bowie, 1987b; Donaldson, 1854; Gamier, 1896; Hartlib, 1646; Jones, 1967; Overton, 1985; Parker, 1975; Young, 1786 than passive through farmer-to-farmer extension mechanisms; and there is considerable evidence that technologies, once adopted, were the focus of experimentation so as to make the appropriate adaptations to suit local conditions.

Farmer-to-farmer Extension

Farmers spread technical knowledge through rural tours and surveys, publications, farmers' groups and societies, open days and informal training.

Farmer tours, visits and surveys

The first systematic attempt to survey farming practice in Britain was undertaken by the Royal Society in 1664. In order to investigate 'what is known and done already … and … what further improvements may be made in all the practice of husbandry', a questionnaire of some 50 open-ended enquiries was circulated to farmers throughout Britain (Lennard, 1932; Thirsk, 1985). Only 11 replies survive, and these describe the various ploughs in use; the uses of different mixtures of lime, marl, seasand, seaweed and manures for different soils; the many varieties of cereals; the use of clover, and the preference of farmers for using 'seed grown in a … soil … at least different from the nature of that ground where they intend to sow it' (Lennard, 1932).

A step forward from this academic exercise was for the principal investigators to make rural visits themselves. The 1700s were an age of global exploration and colonial expansion, and travel itself became a symbol of intellectual growth and moral discovery (Rogers, 1971). Travel became easier too, with improved roads, more comfortable coaches and improved supply of fresh horses at inns. However, even the fastest stagecoaches could travel at only 12–15km/hr, and the smaller parish roads were frequently impassable during winter and in wet conditions (de La Rochefoucauld, 1784; Addy, 1972). In the early part of the 1700s surveyors tended to focus on urban life, particularly the activities of the royal courts and aristocracy, but by the end of the century the focus had shifted to the countryside and to the method of surveying itself.

Daniel Defoe toured Britain in the 1720s and wrote of the economic and social conditions he observed (Defoe, 1724). Despite his eye for detail, his focus was at regional rather than farm level and he commonly missed local diversity; parts of Suffolk, for example, were 'applied chiefly to corn' or 'wholly employed in dairies'. In addition, his 'Tour through the Whole Island' was probably a compilation of visits made over many years – it lacks, for example, the detail about daily weather conditions that obsesses later tourers. In contrast, Samuel Johnson studied 'rural salt processing industries whilst his contemporaries studied castles' (Curley, 1976). Johnson insisted that to know life well, he had to see it first hand, regarding travel as essential 'to test the principles had from books' and to regulate 'the imagination by reality, and instead of thinking how things may be, to see them as they are'. Johnson toured Scotland with James Boswell in 1773, Wales in 1774 and made many other short tours that covered most of England (Johnson, 1775; Boswell, 1785; Curley, 1976).

But, despite their attention to reporting, neither Johnson nor Boswell were farmers. Farmers began to tour the country to observe and learn from other practitioners, and to record the practices and experiments they found. The principal objective of the rural investigation, as Arthur Young put it, was 'to display to one part of the kingdom the practice of the other … and to draw forth … spirited examples of good husbandry from obscurity' (Young, 1769).

The most renowned touring farmers were Young and William Cobbett. Young toured first as an individual interested in the activities of other farmers, and later as an official of the Board of Agriculture. Cobbett began his 'Rural Rides' the year after Young died. Both established durable reputations on the basis of the knowledge gathered on these tours. But they were not alone as touring farmers: the well documented include Robert Bakewell who toured for 2–3 months every year (Pawson, 1957); George Cully, who also often noted in his letters that his neighbours were away on tour to observe agricultural practice (Culley, 1790; MacDonald, 1977); Boys and Ellman, two Kentish farmers, who travelled 1100km in 27 days in eastern England observing livestock management and cropping practice (Boys and Ellman, 1793); the de La Rochefoucauld brothers who made short tours in Suffolk and Norfolk and longer ones in the Midlands and North (Scarfe, 1988), and Richardson, Redhead and Laing who toured Scotland and western England studying sheep (Richardson, 1793; Redhead and Laing, 1793).

As tours became more common attention turned to the approach used for touring, so as to improve learning. Tourers were sensitive to local conditions and the farmers themselves and cautious over claiming too much from their findings. Though Young travelled some 9700km in his first three tours, his concern over possible sampling biases made him cautious about the representativeness of his findings (Young, 1768, 1769, 1771). One condition of reading his reports was that the reader 'pardon the incorrectness of hasty letters; written from inns, farmhouses and cottages, with accuracy in nothing but the matter of my inquiries … You must not expect the authority of such a journey as mine to be equivalent to a general and comprehensive view of the whole island' (Young, 1769).

However, Young has been criticized for adopting conversational methods of research (Kerridge, in Overton, 1984a) and relying on 'mere opinion of the prejudiced' and the 'bare assertions of guarded, or perchance designing men' (Marshall, 1808, quoted in Allen and O'Grada, 1988). William Marshall asserted that the tourer gained only a transient view of rural life, understanding 'a few particulars of practice that may happen to be going on at *the time of his tour*' (his emphasis) (Marshall, 1818). Tourers were 'raw observers' unless they had a depth of practical knowledge of the area to be surveyed. He believed it was best to live with a well-informed farmer for at least a year, so as to 'minutely observe the living practice which surrounds him [the farmer]' (Marshall, 1818).

Young was, however, aware of the need to crosscheck by triangulating the information he gathered: 'I met with some farmers who gave me accounts too improbable to credit … but always repeated my enquiries upon those occasions' (Young, quoted in Allen and O'Grada, 1988). Young drew attention to the benefits of careful observation: 'I have seen many men, who view the farms of other people, apparently for no other purpose than to seek opportunity of talking of their own … You walk through a whole farm with such people, without their acquiring one idea … I was once with a party viewing a farm. Two gentlemen … were so diffuse in describing their own farms and management that it was with the greatest difficulty that poor Reynolds (the farmer) could gain the least attention. When … they went, I requested to go back to a crop of his turnip-rooted cabbage, which we had passed without notice, owing to the volubility with which I was so ill entertained. Various particulars I then gained, highly deserving attention. I afterwards met one of those gentlemen in London, and could not but smile at finding that he was perfectly ignorant even of the existence of the plant in question, of which he might have … been informed of every circumstance of its culture if he would for a few minutes, have given attention to the objects before him' (Young, 1793a).

William Cobbett was also determined to find out the 'real state' of the countryside. Writing after his first day's travel from London, his view of observations made from roads are clear. In spite of drizzling rain, he said: 'It is true that I could have gone to Uphusband by travelling only about 66 miles, and in the space of about eight hours. But, my object was, not to see the inns and turnpike-roads, but to see the *country*; to see the farmers at *home*, and to see the labourers *in the fields*; and to do this you must go either on foot or on horseback' (his emphases) (Cobbett, 1830). He travelled by horse along the lanes and paths, talking to people, stopping at cottages. He was aware that this behaviour was unconventional: 'They think you are mad if you express your wish to avoid turnpike roads … I have crossed nearly the whole country from the northwest to the southeast, without going 500 yards on a turnpike road, and, as nearly as I could do it, in a straight line' (Cobbett, 1830).

Bad weather did not stop these tourers from talking to farmers and labourers in the field, who could not themselves stop work just because of the rain. On a wet day in August, Cobbett recorded that 'I made not the least haste to get out of this rain. I stopped, here and there, as usual, and asked questions about the corn, the hops, and other things' (Cobbett, 1830). Young was also more concerned with learning from farmers than with physical comfort. On the last day of a short tour of Norfolk, one of his two French colleagues recorded that 'it rained so much that, to tell the truth, one could hardly think of agriculture' (de La Rochefoucauld, 1784). But Young stopped at the farm of Mr Toosey, took 'a hasty walk over his excellently cultivated farm', and recorded four pages of detailed findings – in which the weather was mentioned not once (Young, 1784a).

Professional surveyors

The professional surveyor also played an important role in the extension of new technologies. They were farmers employed periodically by landlords to survey tenants' farms in order to establish the conditions, or covenants, of the lease, calculate the financial equivalent of improvements made by tenants, and suggest appropriate rents. The method of surveying was 'to view every piece of the land contained in each farm' and record in detail all aspects of farming and land management (Sayer, 1747; Peak, 1799). Sometimes tenants were found to be in breach of covenants: Arthur Biddell recorded in the 1820s that the 'cropping of field 11 of Mr. Fuller's farm has been contrary to covenants and good husbandry', and that 'a large part of muck which remains on the farm should be laid on Field no 2' (Biddell, 1828). A valuation by Mr Utton of the estates of Sir Philip Broke said one farm was capable of considerable improvement as 'it lies extremely well for getting manure from Ipswich, but little or no advantage is taken of it' (Utton, 1848). By also applying marl and chalk, and adopting the four course system more cereals, turnips and artificial grasses could be grown, and so more livestock kept: 'Each farm could be greatly benefited by carrying more sheep.' The landlord was recommended to make arrangements to pay back a sum equivalent to those improvements made but not yet benefited from, so giving each tenant every 'inducement to … make all (the manures) he can' (Utton, 1848).

Sometimes these reports go further and recommend the tenant visit other farmers to observe the effect of their improvements. Another Suffolk surveyor, Mr Brolter, having recommended the use of clay, marl and ashes, also noted their use was common in the neighbourhood and that the farmer should look himself: 'these improvements would impart financial benefits, besides it would add to the beauty of the prospects from the house' (Brolter, 1790).

Books, magazines and newspapers

The results of many of these surveys were published in books and journals, so giving farmers elsewhere the opportunity to learn of advances. Farmers also had access to agricultural information in newspapers, magazines and pamphlets. The period of the agricultural revolution saw a remarkable increase in these sources of information: in the period 1550–1600 about 2–10 new books concerning agriculture were published per decade; by 1700 this had grown to 20–50, and by 1800 to 150–400 (Donaldson, 1854; Perkins, 1932; Canney and Knott, 1970; Sullivan, 1983).

The quality of writing changed too. Whereas in the 16th–17th centuries authors tended to offer maxims and advice (see for example, Tusser, 1557; Markham, 1631) or to be urban-based lawyers, merchants, court officials and academics (see Donaldson, 1854, *passim*), books came increasingly to be written by farmers and based upon first-hand observation and experience. The first author to record experiments was Adam Speed (1626), who discussed trials with clover, carrots, turnips and parsnips. In the 1640s Samuel Hartlib published the correspondence of farmers, recording their experiments and improvements with green manuring, lucerne, turnips, flax and clover (Hartlib, 1646; Thirsk, 1985). A Mr Buckner was studying a hundred varieties of grass, the Earl of Southampton the impact of planting thousands of fruit trees in hedges, and a Mr Middleton the keeping of mulberry trees, silkworms and the weaving of silk. The detailed records were of individual improvers who were neither writers nor sometimes even literate. As Joan Thirsk has put it 'at all times Hartlib was alert to recommend in his papers any names mentioned in his hearing of men and women who wrote nothing …, but were practical improvers' (Thirsk, 1985).

Some authors, such as Jethro Tull (1731), wrote to publicize their 'inventions', whilst others toured before they wrote: Edward Lisle (1757) visited farms in Wiltshire, Hampshire and Leicestershire to ask farmers and labourers questions on all aspects of farming practice, 'how to burn lime, how to improve meadows, what plough was best. He stopped farmers at work in the fields, and asked them why they did certain things; he experimented at home with the early sprouting of barley and oats, and so on' (Thirsk, 1985). Arthur Young published his first book in 1767. He was always comprehensive, documenting for example more than 500 experiments in the four volumes of the Farmers' Tour of 1769. He was criticized by some contemporary agricultural writers for including details of both successful and unsuccessful experiments (see Gazley, 1973). He maintained, though, that his books were better because they were founded upon experiments and journeys, and was critical of books that had 'only the inferior part of the experiments, that is the remarks and conclusions: so that we have only the author's reflections, instead of that authority which enabled him to reflect; and from which we might draw very different conclusions. Hence arises the difference … the experiment is truth itself, the author's conclusions, matters of opinion, which we may either agree to, or reject, according to our private notions' (Young, 1767). By the late 1700s standards were thus higher, the detail greater and books were treated more as basic references (Thirsk, 1985).

Another contribution to extension was the introduction of journals devoted entirely to the views and practices of fanners. The *Annals of Agriculture* appeared in 1784 and continued for 45 volumes until 1815. Although about a quarter of the articles were written by Young himself, the content ranges from reports of experiments, minutes of tours, details of observations, recommendations for new practices, and general discussion on the state of British agriculture and the countryside. This journal was soon followed by other national journals and periodicals, including the *Commercial and Agricultural Magazine* in 1799, the *Farmers Magazine* in 1800, *British Farmers' Magazine* in 1826, *Journal of Agriculture* in 1828, the *Mark Lane Express* in 1832, and the *Journal of the Royal Agricultural Society of England* in 1840 (Goddard, 1989). As the more practical and experiment-based style became increasingly popular, so farmers could more readily calculate whether an innovation might be relevant to their particular conditions.

However, the number of farmers directly reached by these books and journals may not have been large. The circulation of *Annals*, for example, was of the order of several hundred in the early days, rising later to a few thousand. The most successful book was *Young's Farmers' Kalendar*, which was issued in ten editions in his lifetime, the fifth selling out of 2000 copies within a few weeks of its issue in 1804 (Gazley, 1973). The best agricultural newspapers, though, had larger audiences, selling 4000–6000 issues weekly (Goddard, 1989). Local newspapers rarely covered innovations in detail, though the *Newcastle Courant*, for example, did record the release of ducks into turnip crops to control caterpillar pests, mint in haystacks to keep out mice, and intercropping radishes with turnips to reduce the impact of turnip fly, and carried advertisements for new machinery, new seeds and new drainage techniques (MacDonald, 1977).

Farmers' groups

Farmers' groups that transferred knowledge by word of mouth or by direct observation were even better than the printed word. These were first established in the 1720s, growing more common over the next century. Some were small with a local focus, others larger and acting at a national level. Most held regular meetings and occasional shows and fairs, and sought to encourage innovation by offering prizes. But the turnover was considerable. Those that tended to succeed were established by groups of local farmers themselves, rather than imposed by outsiders, or had access to outside financial or patronage support.

The earliest agricultural society in Europe was the Society of Improvers in the Knowledge of Agriculture in Scotland, established in 1723 (Ramsay, 1879; Handley, 1963). It distributed advice to members, such as on types of manures best suited to their soils, new crops and deep ploughing, but more importantly it encouraged each member to form small associations in their own districts for 'the diffusion of better methods of farming' (Handley, 1963). The East Lothian Society, for example, met monthly in a village inn, and grew to have 122 farmer members. The poet Allan Ramsay celebrated the vision of farmers' clubs by suggesting that improvements would lead to such an increase in productivity that rents could be tripled, 'without the purches of one acre more' (Withers, 1989). But the society closed after 20 years when a key figure in its success, Mr Maxwell, died. In 1754 the Edinburgh Society for the Encouragement of Arts, Sciences, Manufactures and Agriculture was established to offer premiums, or prizes, for good practice. In 1756 Mr Walker won the prize for 'the tenant who should produce the greatest variety of marls and other manures, with a short account of the places where they were found, and the uses to which they were applied' (Ramsay, 1879). But it closed in the mid 1760s. Societies were most insecure following the ill health, departure or death of a leading figure.

Two societies of national importance that did survive were the Society for the Encouragement of Arts, Manufactures and Commerce (later the Royal Society of Arts) and the Highland and Agriculture Society (HAS), established in 1754 and 1763 respectively. Both offered premiums for innovations, and took a systematic view of farming, in which the context of production and the circumstances of each farmer were central. Thus in 1772 the former offered prizes to determine the value of carrots, cabbages, turnips and potatoes for fattening livestock. Prizes encouraged experimentation, though they did not always resolve an issue. On sowing lucerne by broadcast or by drilling, Young commented 'as a sufficient number of experiments has not been published to prove which of these methods is most advantageous, the Society very judiciously leaves it to the cultivator's private judgement' (Young, 1767). The HAS may have been more effective in extension as it strongly promoted local associations. In Scotland 60 associations were established by members (Handley, 1963). Some were at village level: the Lunen & Vinney Farming Society of Dunnichen village was established by George Dempster, membership rose to 80, and the society brought yellow turnips and drilling of wheat to their locality. The final meeting was held in 1814, when Dempster was 80 years of age. The HAS itself survived because of the patronage of Sir John Sinclair, chairman of the Board of Agriculture, who gave them an annual grant of £800 per year, so helping them obtain a Royal Charter.

Local societies also grew rapidly in England. First were the Manchester, Norfolk, Bath & West and Sussex in the 1760s and 1770s, but by 1820 the total had grown to 50, and by 1840 to more than 400 (Goddard, 1989). The principal interest was again the award of prizes, usually at local shows and typically for new and/or high quality livestock, crops and machines. The Bath & West was particularly innovative, purchasing land to set up on-farm trials for new practices. During the 1830s Farmers' Clubs became popular in the promotion of improvements and diffusion of information (Fitzgerald, 1968; Goddard, 1989). These clubs held regular discussion meetings, established libraries and arranged visits to well-known farms.

The establishment of the Royal Agricultural Society of England (RASE) in 1838 marked the end of this agricultural revolution in internal resource use. As I shall discuss below, this society signalled the end of an era in which farmers' knowledge was accepted as best. From the 1840s, scientists off the farm gradually displaced farmers as technology generators, diffusers and experimenters.

Open days and fairs

Farmer groups also held occasional open days to publicize new farming practices and breeds of livestock. The most well-known meetings of this period were the 'sheep shearings' of the Duke of Bedford and Thomas Coke, at which there were often several hundred people present (Young, 1799, 1803, 1808). Of the 1799 open day at Bedford's Woburn farm, Young said 'it was the greatest meeting of the kind ever seen in England … A great assemblage of farmers, breeders and graziers from every part of the kingdom … in which the conversation was entirely agricultural' (Young, 1799). The open days at Coke's farm at Holkham ran annually between 1778 and 1821. Prizes were awarded for the best agricultural implements and livestock, information was exchanged on cultivation techniques and the performance of new crops, and ploughing matches were held. Farmers were also able to observe the practices on the estate, renowned for its rotation system that could feed 1500 sheep with no resort to permanent pastures or meadows.

Agricultural training

In a period that lacked formal agricultural training as well as extension institutions, farmers developed their own informal training networks. It was common, for example, for farmers to send their sons in their late teens or early twenties to spend a year in a progressive region (MacDonald, 1977). George Culley, an improving farmer and stockbreeder, frequently housed 8–10 students, and indicated in his letters that his neighbours did likewise (MacDonald, 1977). In some cases farm workers travelled to learn a specific technique – the first watermeadows in Northumberland were constructed on Culley's farm in the 1780s following a visit by one of his workers to George Boswell's farm in Dorset (MacDonald, 1977). Others learnt on the farm: a ploughman at Kelso who learnt how to drill turnips from his employer, who had himself spent 6 years in southern England, then spent 13 years as both ploughman and instructor of apprentices. When he leased his own farm he had an even greater impact on diffusion 'as a farmer paying rent, and acting at his own risk, had an immediate influence, as to the … rapid diffusion of turnip … husbandry among practical farmers' (MacDonald, 1977).

A government extension agency

Government agricultural policy was so dominated by promoting enclosure that little attention was paid to supporting farmer extension mechanisms. The Board of Agriculture, established in 1794, was charged with 'making every essential inquiry into the agricultural state, and the means of promoting the internal improvement' (Young, 1804), but despite Young being Secretary, it was underfunded and had too little support from government. It commissioned surveys for each county, but the surveyors were not necessarily farmers, and the results were patchy. Some were short and poorly written – only 38- and 34-page reports were produced for Shropshire and Rutland (Bishton, 1794; Crutchley, 1794), whilst others were much more comprehensive – 286 pages for Norfolk and 168 pages for Staffordshire (Kent, 1794; Pitt, 1794). New surveys were commissioned, but financial support to the surveyors and for publication was again inadequate. The Board closed in 1822, having succeeded only in sponsoring premiums and lectures, publishing articles and influencing government policy on taxes, weights and measures (Goddard, 1989).

Technology Adaptation

These extension mechanisms brought new knowledge to many more farmers. Yet knowledge of an innovation does not imply adoption. Farmers, once exposed to an innovation, still had to decide whether to adopt according to locally perceived incentives and constraints.

Incentives to adopt

The overriding incentives to adopt a new technology relate to the investment required and the perceived rate of return. An innovation requiring no new training or capital investment and bringing returns in the same season would be favoured over one that was costly, risky and producing benefits far in the future. Bringing quick returns for low investment were fodder crops, intensified rotation patterns and manures; livestock breeding was not costly, yet it could take time to produce the desired animal; but new machinery, drainage and irrigation required much greater investment.

Changes in prices could affect these perceptions. The increase in value of livestock products relative to cereals in the early 18th century favoured diversification, so increasing fodder and manure production (Beckett, 1990). Greater diversity on the farm also meant lower risk of complete harvest failure. But to adopt new technologies farmers required some security of tenure. Tenant right guaranteed them financial returns for the unexhausted improvements they made, but was only common in southeast and midland England. Thomas Moses, an improving and experimenting farmer of the 1820s–1840s in Lincolnshire, farmed on an annual lease with no covenants, except that he farmed 'in a tenant-like manner' (Beastall, 1978). To ensure he would receive full compensation on quitting the lease he recorded details of all improvements – repairs to farm buildings, stables, fences, ditches and roads; the purchases of ploughs and harrows; the planting of trees; and the establishment of a kitchen garden. Short leases, although a disincentive to invest when there was no tenant right, could easily be changed to account for new technological opportunities.

There was also a gradual change toward granting of long leases – Coke granted them for 7, 14 and 21 years so as to encourage investment. As James Caird, a later tourer, put it in 1852, 'the investment of a tenant's capital in land seldom contemplates an immediate return. He does not anticipate that a large expenditure in cleaning and enriching worn-out land will be all repaid to him in the first crop. He lays the foundation for a series of good crops, which in the aggregate he expects to repay him with interest If he drains, makes fences, or other improvements of a more permanent character, a still longer period is requisite to compensate him' (Caird, 1852).

It has been long assumed that the conversion of open fields to private property farming was in itself an added incentive to adoption of new technologies – potential improvers could not fight the inflexibility of collective decisions that stuck to tradition. But open fields did not necessarily prevent innovations, nor enclosure encourage them (see Havinden, 1961; Turner, 1986). Enclosure was not a direct incentive to improve, though it did allow for the rewriting of leases and raising of rents (Beckett, 1990). There remains widespread disagreement over whether productive gains occurred following enclosure – some have suggested output gains of 50–100 per cent (Wordie, 1983), others a modest 10–15 per cent (McCloskey, 1975), and others still that enclosed farms were no better than open (Allen and O'Grada, 1988).

Constraints to nationwide adoption

As I have described, there were commonly delays of 100–200 years between invention and widespread adoption. Technologies became common in restricted localities, but did not spread. Yet as rural Britain was so diverse such widespread coverage should not be expected. Kerridge and Thirsk have suggested there were 38 to 48 distinct farming zones in England and Wales, comprising mixtures of subsistence and market-oriented, pastoral, arable, dairying, special livestock enterprises, market gardening, meat rearing, woodland and pasture (Thirsk, 1987; Kerridge, 1967). Before passing from one zone to another technologies required widespread testing and adaptation. As Joan Thirsk put it 'new agricultural crops and methods could not find their niche within varied farming systems without undergoing a long process of trial and error that could involve many delays and setbacks' (Thirsk, 1987). But within zones diffusion could be slow if the improvement was costly or risky – after Culley established watermeadows on his farm it took 'near 20 years before any other person ventured to pursue the practice, and profit by the example. It is now beginning to spread in the neighborhood' (Bailey and Culley, 1805).

If agricultural labourers were against change, their unwillingness could put an end to innovation. This was particularly true for ploughs, drills or threshing machines that reduced or changed the labour requirement of workers who had spent years developing skills (Collins, 1969). New ploughs sent by Sir John Delaval to his estate did not meet with his ploughman's approval, who suggested the wood was twisted or green (MacDonald, 1977). But given the opportunity of observing the advantages of a new technology, adoption could be rapid. Reapers in Berwickshire in 1790 quickly adopted the scythe as a alternative to the sickle when they were outpaced by imported labourers (MacDonald, 1977).

Not all innovations succeeded in eventually being adopted nationwide. Dye crops, such as madder and woad, were experimented with in the 1600s, but did not spread as they represented too great a financial risk; tobacco was cultivated despite a government ban that aimed to encourage cultivation in Virginia, but it too died out, probably because it was too labour-intensive; liquorice was common around Pontefract and Worksop, but did not spread (Thirsk, 1985). The intervention by government in tobacco cultivation was rare – generally it neither directly supported nor hindered the adoption of new technologies.

Attitudes to experimentation

There is considerable evidence to indicate that farmers, once they adopted one of these new technologies, experimented to make the changes necessary for its adaptation to local conditions. They conducted field trials to test the efficacy of various manure and nutrient treatments on soils; they tested corn drills against other methods of seed sowing; they introduced new crops into rotations on some fields, whilst leaving others unchanged; they tested irrigated against dryland meadows; and they tested new methods of pest control. As Caird put it 'the detail is everywhere varied by the judicious agriculturalist to suit the necessities and advantages of the particular locality' (Caird, 1852). Farmers were concerned with integrating the results of experiments into their farm economies, and so analysed results to discover which were the most profitable options. To many, experiments were seen as a necessary part of farming. They did not expect to resolve issues once and for all, but rather saw them as part of an adaptive performance in the face of unpredictable climatic and market conditions (see Richards, 1989).

Many experiments were conducted first in kitchen gardens where they could be protected and monitored, and if successful then spread to the rest of the farm. In the 1780s a farmer discovered a single very productive ear of wheat in a hedge; he carefully cultivated it for four years in his garden, and by the mid-1790s this variety of 'Hedge Wheat' was said to be 'widespread and superior' (Goldhawk, 1795). The success of kitchen gardens as sites for experimentation was clear during the 1600s as commercial gardening grew rapidly to supply new vegetable and fruit crops to cities. London became surrounded by market gardens – their area growing from 4000 to 45,000 hectares between 1660 and 1720 (Thick, 1985). Innovative technologies and techniques were pioneered in gardens, such as row cropping of carrots, beans and peas to facilitate hoeing of weeds; new flower, fruit and tree crops brought from abroad; hot beds of still decomposing manure and compost put into long beds one metre high and broad for the cultivation of radishes, mushrooms, cucumber and asparagus; and the use of glass cloches to extend the growing season (Thick, 1985).

The practice of continuous experimentation was widespread, and the people who knew best how to conduct them were the farmers themselves. Farmer knowledge was recognized by de La Rochefoucauld on his visit to Suffolk: 'the knowledge which all these farmers possess is incredible – you must see them to realize how simple farmers can talk for an hour on the principles of their calling and on the reasons underlying their various forms of cultivation' (de La Rochefoucauld, 1784). Young said that 'experiment is the rational foundation of all useful knowledge: let everything be tried' (Young, 1767). He published *Experimental Agriculture* in 1770, comprising some 900 pages of detailed results of five years of experiments on 120 hectares of various soils. He had begun confidently expecting conclusive answers, but concluded the task in a different mood: 'I entered upon the following experiments with an ardent hope of reducing every doubtful point to certainty; and I finished them with the chagrin of but poorly answering my own expectations. Where I imagined 2 or 3 trials would have proved decisive, 40 have been conducted in vain' (Young, 1770). Bakewell's approach to experiment was openminded: 'I would recommend to you and others who have done me the credit of adopting my opinions to pursue it with unremitting zeal as far as shall be consistent with prudence and common sense, always open to conviction when anything better is advanced' (Bakewell, 1787, in Pawson, 1957). And Culley, in a letter in 1801, wrote 'I often say that we have a deal to learn yet. And every wise humble man will learn every year and every day' (MacDonald, 1977).

And yet these considered comments of farmers seem to have been very largely forgotten since the end of the agricultural revolution. They conflict with the predominant view of the agricultural experiment, namely that it is the domain of scientists and takes place solely on the research station or in the university. Orthodoxy holds that scientific agriculture began with the establishment of the RASE in 1838 and Rothamsted Experimental Station in 1843. These have brought immense benefits to agriculture, but have also served to hide the experimental practices of farmers. The result is now a deeply held belief that the first scientific experiments occurred only after the 1840s. A recent history of agricultural science in Britain begins at 1840 (Rossiter, 1975); and two earlier books by E. John Russell, a former director at Rothamsted, suggest that the 'first experiments' began in earnest at Rothamsted, before which any experiments were conducted by academics working alone. In neither of his books is the role of farmers mentioned (Russell, 1946, 1966).

Experiments to improve soil fertility

Experiments to improve and sustain soil fertility promised quick returns for relatively little investment, and farmers made use of both internal and external resources (Table 12.2). Some had been common for centuries – livestock manures, marling, leaf mould and lime certainly had long been crucial in maintaining soil fertility and physical structure (Pretty, 1990c). Some experiments were designed to test various treatments over time on the same field. Having grown nitrogen-fixing tares (vetch) before wheat and producing 'excellent crops' as a result, the Rev. Moseley of Drinkston felt that something further could be done in the three months between the vetch harvest and wheat sowing in order 'not only to keep the land clean, but to improve the succeeding crop' (Moseley, in Young, 1813a). He planted buckwheat (*Fagopyrum esculentum*) and ploughed it in as a green manure. The wheat benefitted, but as it was attacked by rodents on the threshing floor, he conducted the experiment again the following year. This time he harvested 3.3 tonnes from 2.4 hectares, a 'much larger crop than I expected'. Young commented that 'many have sown tares; and many have ploughed in buckwheat; and most have given a year to each; but it is the combination of the two that forms the merit … Mr Moseley in this husbandry is original' (Young, 1813a).

Other experiments were designed to compare the relative value of different treatments on the same field. In 1818, Arthur Biddell, a tenant farmer at Playford

Table 12.2 *Technologies for sustaining, restoring or improving soil fertility used during the agricultural revolution*

From within village community

- Livestock manure
- Green manure crops
- Seaweed, ploughed in green
- Nitrogen-fixing crops
- Compost heaps of weeds, rushes, bracken, old thatch
- Fish such as pre-rotted sticklebacks, pilchards, sprats
- Ashes
- Peat and turves
- Pond mud
- Soot
- Old clothing and footwear
- Leaf mould from woodlands
- Sand
- Pigeons' dung
- Fruit pulp
- Sawdust

From outside village community

- Night soil from cities and towns
- Other refuse from cities and towns
- Industrial wastes, including pulverized slags, soap, ashes, waste bark from tanneries, shoddy from textile factories
- Oil cake (from crushed seed of coleseed)
- Bone meal

Sources: Mingay, 1977; Kerridge, 1967

in Suffolk, described an experiment on a wheat field divided into six small plots (Biddell, 1817–21). The plots were treated with 2lbs of salt, 1 bushel wood ashes, 1 bushel fine cinders, ammonia tar water and tar, and soap boiler's ashes, with a sixth control having no manure. Unfortunately there is no record of which treatment performed best, though he did record in another memo that all cereal harvested from experimental plots was taken to separate threshing sites so that yields could be measured and compared. In 1823 he described a complex experiment involving treatments for barley cultivation according to sowing method, manure type and freshness of the manure (Biddell, 1821–24). The treatment for each of the 13 sections of the field varied according to sowing technique (drilling or dibbling), manure freshness (straight from the stable door or exposed for a month), manure type (horse manure, sprats), and order of treatment (manuring first or sowing first). He indicated the 'best corn after the 70 bushels of sprats'. Figure 12.1 is a reproduction of another experiment to compare manuring with ashes, livestock manures and green manuring.

Some farmers experimented in order gradually to improve patchy quality fields. Thomas Moses's experimental approach on his Lincolnshire farm produced

Figure 12.1 *Experimental layout for wheat treated with ashes, livestock manure or composted green tares (vetch) grown on the four-hectare Holly Bush field on the farm of Arthur Biddell at Playford, Suffolk, 1819. Reproduced from Day Book No. 2.*

the best yields of cereals and turnips in the region having begun with some of the 'poorest pieces in the lordship' (Beastall, 1978). One field of 16 hectares was renowned for its heterogeneous soils – yields were generally poor, but varied widely across the field. He began by applying bones, ash, lime and manures in 1829, and then grazing it for two years; it was then partly underdrained and partly marled; by 1839 a good oat and wheat crop was recorded. In 1840 more marling, manuring and bones produced 'excellent turnips', the next year excellent barley and oats too. In 1843 the remainder of the field was underdrained and further marled. In 1845 the consistency of crops was now the same across the whole field, and in 1846 barley yielded at 3.5 tonnes/hectare.

Experiments with rotation patterns

Intensification advanced significantly with the introduction of root crops, including turnips, carrots, potatoes and swedes, and true and 'artificial' grass mixes, which included some 5–10 new grass species, nitrogen-fixing clovers, trefoils and sainfoin and burnet and rib grass.[2] The Norfolk Four Course rotation has become a classic model of intensification in the agricultural revolution. The introduction of roots and clovers permitted a change from spring cereal–winter cereal fallow to spring cereal–clover–winter cereal–root crops. Thus the proportion of land devoted to cereals declines from 66 per cent to 50 per cent, but for fodder crops it increases from zero to 50 per cent. But this idealized pattern was rarely adopted without some local experimentation and adaptation. On his 75-hectare farm Biddell continually changed the pattern to suit his needs. Sometimes it closely reflected the Four Course, as in Holly Bush field between 1807–17, but then an extra wheat crop is slipped in after beans in 1810 (Table 12.3). On Paddock field by comparison, wheat is grown in five out of seven years between 1807–13. In the second period the pattern is more varied, as an increasing number of crops are tested. In all he grew 28 different species of crops, with a maximum of 14 in any year. Of the introductions coleseed, flax, lucerne, sainfoin, hemp, wurzel, white and Swedish turnip, and Gold of Pleasure were grown for less than 3 years, and appear to have been rejected as unsuitable; whilst carrot, potato, tares, trefoil, red clover, radish, beetroot, rye grass, swede and mustard were absorbed into the rotation pattern (Biddell, no date). But despite this experimentation he did not greatly vary the proportion of land devoted to each of four classes of crop, namely cereals, roots, legumes and grasses plus miscellaneous vegetable and fibre crops.

This impression of local adaptation is further strengthened by the rotation patterns recorded elsewhere in Suffolk – in the County Report Young records 24 different variations in the Four Course rotation (Young, 1813a). Nonetheless, not all farmers were experimental. Two neighbours of Biddell's followed unvarying patterns: one rotated wheat-ley-barley-clover or beans, with an equal proportion of each crop on his 15 fields; and another kept to an unchanging Four Course pattern involving winter wheat–ley–spring cereal–legume, only very occasionally inserting a crop of peas or rye (Cooper, 1827; Pettite, 1830).

Not only did farmers experiment with the type of crops grown, they also carefully analysed profitability. Coke relied solely upon roots and artificial grasses to feed his sheep. Already convinced of the benefit of sainfoin, and wanting a replacement for red clover, he set aside a 12-hectare piece of land in the middle of a large clover and rye grass field to experiment with trefoil, white clover, cow grass, rib grass and burnet. In the first year Coke observed that the sheep voluntarily fed on the new crops. The first two trials were successful and by the third year he had extended the experiment to 90 hectares. Having observed the experiment Young said 'this is in truth doing justice to the new husbandry, by practising it with a spirit formed to establish it on the unerring dictates of experience' (Young, 1784a).

There were other experiments too. Bakewell repeated for several years an experiment to determine both the best fodder crop and method of harvesting. He sowed five strips in one field with rye grass, red clover, white clover, red/white clover mix and red clover/rye grass mix, and then overlaid these by mowing or grazing by cattle or sheep – the most productive treatment was mowing the red clover/rye grass mix (Pawson, 1957). And Young himself kept permanent experimental grounds

Table 12.3 *A Sample of crop rotation patterns on five fields of the farm of Arthur Biddell, Playford, Suffolk for the periods 1807–1817 and 1840–1850*

Years	*Fields*				
	Holly Bush	*Lollys*	*Paddock*	*Thistley*	*Church Field*
1807	Tu	W	W	Be	W
1808	B	Tu	W	W	B
1809	Cl	B	w	Tu	Lu/Ta
1810	W	Ta	Be	B	B/Be
1811	Tu	W	W	Cl	O
1812	B	T	Cl	W	Cl

on his farm. As the two touring farmers, Boys and Ellman, recorded in 1793, 'in Mr Young's experimental ground are several patches of about a perch each, of many sorts of grasses, amongst which the meadow fescue and *Alopecurus pratensis* seem the best; timothy tolerably good; peas bad; *Avena elatior* very strong but coarse' (Boys and Ellman, 1793).

It is rather surprising that given all this evidence of experiments with new crops there is relatively little on mixed or multiple cropping. The practice was certainly common in the Middle Ages, with cereals grown together with other cereals and/or legumes (Pretty, 1990c). Sometimes the mixtures were both more productive and less risky than the individual constituents of the mix. Yet limited evidence from early 18th-century probate inventories in Essex does indicate that about a third of all farmers chose to grow various mixes of barley, oats, peas and vetches (Steer, 1950).

Farmers did swap seeds to maintain genetic diversity. In Suffolk it was common for farmers on light sandy soils near the coast to swap seed corn with those on heavier soils of central Suffolk, thus avoiding merchants, who were suspected of mixing of seed stocks in their stores (Evans, 1960). In 1821 Biddell planted one field to wheat in four strips, the first with wheat from a Mr Fuller, then a Scotch variety from Mr Elys, the next to a North Country variety, and the last to 'wheat of my own growth' (Biddell, 1821–24). Later, in 1823, the wheat grown is his own, Scotch wheat from Mr Branson of Stromland, Kentish Red wheat from Mr Catlins of Battley Abbey, and another red variety from Mr Dicksons of Coddenham (Biddell, 1820–28).

Experiments with sowing techniques

Farmers also experimented with methods of seed sowing by comparing broadcasting the seed by hand, dibbling by making holes in the soil into which the requisite number of seeds were dropped, and drilling with newly invented seed drills. The amount of seed and spacing are important because if too little seed is sown then available water, nutrient and light resources are not fully used, and so can be captured by weed plants; but if too much seed is sown the crop plants then compete against each other, and though the weeds are suppressed yields also decline. The seed drill offered efficient weed control by evenly spacing the plants and so reducing seed requirement – for cereals to 5–15 per cent and turnips to 5–10 per cent of that for broadcast or dibbling (Wilkes, 1981).

The seed drill was invented in about 1600, and effective designs were patented by many farmers, including Bailey, Cooke, Tull, Young, Amos, Blaikie and Garrett (Wilkes, 1981). But technical shortcomings meant they diffused neither rapidly nor smoothly; there were problems with maintaining an even seed flow, balancing the strength of the machine against weight and the expense of production. Reports to the Board of Agriculture and in *Annals of Agriculture* suggest that drill husbandry was being widely experimented with at the end of the 18th century, but was only common in parts of Northumberland, Durham, Suffolk and Norfolk. There were still so few machines by the early 1800s that contract drillers became common – Suffolk farmers hired their drills with skilled labourers to farmers in Cumberland and Scotland (Wilkes, 1981).

During the agricultural revolution drilling was continually tested against the other techniques, all of which were often practised side by side on the same farm.

Table 12.4 *Results of experiments conducted on the farms of Thomas Coke of Holkham and Rev. Dr Hinton of Northwold, Norfolk, 1790s*

	Yield (kg/ha)	
	Drilled	*Broadcast*
Wheat (at Northwold)	2995	2620
Barley (at Holkham)	2360	2500

Source: Young, 1804

In the County Report for Norfolk, Young records the seed-sowing practices of 44 farmers by name; of whom 21 just drilled, one just broadcast, two just dibbled, and 20 were experimenting with combinations of the three (Young, 1804). The results of experiments varied according to local conditions and crops: for some broadcast was better, whereas for others drilling was best (Table 12.4). Mr Overman of Burnham Deepdale conducted his first drilling experiments with peas in 1790; then in the next year he compared the three techniques; finding the drill to yield 25 per cent more he then drilled all his peas and tried wheat for the first time in the third year (Young, 1804, 1793b). But drilling of barley and oats was not so successful: he tried, stopped, and then tried again.

Farmers also finely tuned each sowing technique. Biddell conducted an experiment to ascertain whether holes should be dibbled 'thick and seeds dropped thin, or holes thin and seeds dropped thick' (Biddell, 1812–16). As a diagram in his work book indicates more holes, each with fewer seeds, was the most productive treatment (Figure 12.2). And a Mr Harper ascertained the comparative benefits of the different sowing methods, including attendant weeding and other labour costs, by splitting a 4.5-hectare field into 8 strips, and conducting a different treatment for each (Figure 12.3).

Experiments with livestock breeding and management

At the same time as these new crops, rotation patterns and methods of sowing were increasing the production of on-farm forage, farmers also experimented with livestock breeding to produce animals capable of more efficient conversion of feed. Robert Bakewell, though not the first selective breeder, was the first to apply precise methods to produce early maturing meat-producing animals that would transmit these properties to offspring with certainty (Pawson, 1957). He aimed to 'fix the type' by establishing in his mind a clear picture of the desired animal. By inbreeding, selective culling, careful analysis of food consumption, conversion rates and carcass properties, he developed new breeds of cattle, sheep, pigs and horses. Selecting one or two traits he was able to make great advances, getting beasts to put on weight 'in roasting places, and not boiling places' (Pawson, 1957). But there were trade-offs: his cattle had long horns, and the sheep produced little milk and wool.

Figure 12.2 *Experimental layout to ascertain whether wheat yields are better when 'holes thick and seeds thin' or vice versa. Part of Stock Hill Field, farm of Arthur Biddell at Playford, Suffolk, 1813. Previous crop was clover ley. Reproduced from Work Book No. 2.*

Although his farm was 180 hectares in size and supported 400 sheep, 150 cattle and 60 horses, it was too small to obtain verifiable results for his breeding. He therefore adopted a system of hiring out the best quality males for a season to other farmers, thus transferring genetic material to another herd. To begin with he was ridiculed, and the first ram commanded fees of only 16 shillings in 1760. But the demand for his animals grew as word spread of their attributes, and by 1784 his best rams were fetching a fee of £105 per season. Bakewell could now study the performance of the progeny of these males in herds and flocks of different genetic mixes. But to ensure that the replications were comparable he set strict conditions on each lease to ensure that feeding was natural and not forced. The effect of this system was to spread and extend new stock, whilst allowing him to conduct and monitor experiments on a nationwide scale.

But not all breeders were concerned solely with increased meat output. Sheep flock managers on the Wessex downs wanted economic feeding, mobile sheep that were good 'manure carriers' (Bowie, 1990). In this Hampshire Custom system of

management a rapid turnover of lambs was achieved through a system of internal resource maximization. Sheep travelled daily between pasture and arable fields, and were stocked at a rate of 1200 ewes and lambs per hectare at night. Early lambing in January–February based upon the early grass produced in watermeadows meant that fanners could market when prices were high. Rotations of sainfoin, leys, arable and fallow were locally adapted in an 'infinite number of variations and permutations' (Bowie, 1990). The sheep were shortwools, hardy and economic feeders, though not maximizers of meat. Flockmasters were continually experimenting with cross-breeding by bringing in rams from distant locations. William Humphrey, for example, hired Southdown rams from Cambridge, and produced large sheep with good flesh, and the strength and hardiness to consume root crops on cold hills (Bowie, 1987a). By comparison, sheep on the physically similar Wolds of Lincolnshire and East Yorkshire were relatively immobile longwools, yielding 3.5–5kg wool per fleece compared with 1.5–2.5kg for the shortwools (Bowie, 1990). Here farmers were oriented towards the rapidly developing northern markets, and relied heavily on external inputs and capital, buying bonemeal fertilizer in particular, and did not value sheep manures so highly.

Formal experiments to compare different breeds were also common. The Duke of Bedford compared four groups of 20 Southdown, Leicester, Worcester and Wiltshire sheep over 16 months by feeding them the same amounts of turnips and hay and, assuming the same grass consumption, found the weight gain best in the old breeds (Russell, 1986). Over a shorter period, Count Magzie of Silesia reported that sheep fed with potatoes over winter grew much better than those fed oats (Magzie, 1799). Russell has, however, suggested that the results of contemporary trials should be treated with caution, as design and execution varied widely (Russell, 1986).

Experiments with irrigation

A significant innovation of the agricultural revolution that improved internal resource use was irrigation. Water was diverted from streams and rivers to irrigate meadows, so producing spring growth some 4–6 weeks ahead of dryland meadows, a reliable hay crop in July, and further growth during the late summer. Although costs for surveying, design and construction were relatively high, the returns to investment were good (Bowie, 1987b). The value of the 'early bite' was central to the production of early lambs, and particularly to small farmers for whom 'even a small watermeadow which will produce an early crop of spring feed at the very time of the greatest pressure … must be more valuable to a poor arable farm than can be imagined' (Smith, 1806, quoted in Bowie, 1987b). Winter cereal yields also improved, as livestock were no longer fed off young cereal plants at this time. Hay production from good watermeadows was roughly double that of dryland meadows (Bowie, 1987b).

Bakewell experimented with irrigation to improve grass yields, constructing channels that eventually reached almost half of his farm, and then tested various 'proof pieces', as he called the treatments (Pawson, 1957). In one experiment he divided these into treatments with irrigation, no irrigation, irrigation plus manure, irrigation and no manure, spring water and stream water. He was proud that his livestock were fed exclusively on farm-produced fodder, and that he had invented a further use for these channels, namely the transport, or 'navigation', of turnips. At harvest, turnips were flung into the nearest channel and transported up to a mile distant, arriving clean and washed (Pawson, 1957). Other crops, such as carrots and potatoes, were put on specially constructed boats as they did not float.

Elsewhere, irrigation was valued for the suspended silt it brought. In eastern Lincolnshire, Yorkshire and Norfolk, water was directed into temporary enclosures, or warps, about 2 metres high and constructed from timber, earth or limestone. As the water drained away, so a 15–40cm layer of fertile silt remained (Beastall, 1978; Young, 1813b). The impact of warping on land value was significant, sandy soil improving from £12 to £150–250 per hectare (Beastall, 1978). With the addition of cattle and horse manures, warping fostered the local diversification of Lincolnshire agriculture to market gardening of carrots, onions, apples, peas, potatoes, flax, hemp and hops. Warping farmers also had ready access to transport to distant urban markets as they were close to large rivers.

As with all irrigation systems an ingredient of success is good community cooperation. Warps occasionally broke their banks and flooded neighbours' land; and watermeadows needed agreements before construction. In the Itchen Valley, for example, five farmers agreed not only the collective irrigation of 4.5 hectares of meadows, but also a quota for water allocation based on 7 days and nights each, and operation and management costs for them and their successors (Bowie, 1987b).

Experiments with drainage

Farmers also improved their land by experimenting with new methods for draining wet soils. The traditional method had been to plough ridges and furrows, but now farmers began to dig trenches that were filled with stones or plant matter, and to lay tile drains. In the 1820s James Smith of Perthshire, having laid a network of deep drains on 80 hectares, supplemented drainage with a heavy subsoil plough he had invented for the purpose (Watson and Hobbs, 1937). The land was converted from waterlogged to luxuriant, and 'farmers and landowners came crowding to visit' (Watson and Hobbs, 1937). Friends and neighbours in the Gargunnock Farmers' Club copied his method with considerable success.

Like irrigation, drainage so improved the value of land that incoming tenants were often willing to pay up to four times the former rent. But drainage did not advance significantly until the invention of a machine to make cylindrical pipes in the 1840s. Government then supported drainage by subsiding drainage costs by about 17 per cent between the 1840s and 1870s (Beckett, 1990).

Experiments with handtools

Another target for experimentation was the seasonal peak of labour demand during cereal and hay harvest. Inter-regional labour flows were necessary to meet this constraint, and harvest gangs in England were commonly drawn from Ireland and Scotland and the workforce in the newly industrializing centres, where iron furnaces, forges and mills often closed at harvest as workers returned to the fields (Collins, 1969; Jones, 1967). The opportunity to offset this constraint came with the development of new harvesting tools to replace the sickle. These were the scythe (blade attached to a bow or cradle to assist in the laying-down of the cut), the reap-hook (slightly heavier and broader than the sickle) and the bagging-hook (large, heavy smooth-edge hook with a second hook to tension the cereal), and represented a labour-saving potential of 40 per cent, 15 per cent and 35 per cent respectively (Collins, 1969). The adoption varied by location, and changes to blade and handle design were common.

Experiments with pest control

Diverse genetic stock, a diverse agricultural landscape, and multiple cropping would have checked outbreaks of pests and diseases during this period. But there were few explicit experiments on pest and disease control. Thomas Coke saved £60 worth of turnips in one field after he had gathered 400 ducks to control black canker caterpillars. 'In five days they cleared the whole most completely, marching … through the field on the hunt, eyeing the leaves on both sides with great care to devour every one they could see' (Young, 1784b). In Devon, a farmer wrote of the benefit of fumigating orchards with smoke to reduce pest damage (Gullett, 1786). More common was the treatment of seeds before sowing to reduce fungal or insect attack. In the 1780s, Young steeped wheat seed already black with fungi in various mixtures of water, lime water, wood ashes solution and arsenic and compared the number of smutty ears after a season (Young, 1788). Any treatment of more than 4 hours reduced infection to 1 per cent of that of water or no treatment. Later he describes the benefit of steeping turnip seed in water for 48 hours before sowing to reduce turnip fly damage (Young, 1813a).

Lessons for Sustainable Agricultural Revolutions

The successes and failures of the British agricultural revolution give some indications about the preconditions necessary for fostering sustainable agricultural revolutions today. Intensification of on-farm resources increases crop and livestock productivity, and so ensures that agriculture does not pollute or contaminate the environment (Pretty, 1990a; Conway and Pretty, 1991). Increased production based on internal resources increases the need for labour, and so increases the population-supporting capacity of the land. And more innovations mean more options for farmers to diversify, so reducing the risk of physical or economic shocks and stresses threatening their livelihoods. Most importantly, though, farmers fully involved in the process of technology generation, extension and experimental adaptation more readily make improvements. In the British agricultural revolution all this was achieved without explicit support from government.

At the same time, however, extensification was being strongly promoted even though it destroyed the common property resources that were essential buffers against adversity for those relying on the provisions of fuel, fodder, food and employment opportunities (Hardy, 1887; Collins, 1989; Jodha, 1991). During the agricultural revolution their value was barely recognized. They were called wastes, and represented to many a symbol of backwardness or underdevelopment. Young called those who opposed enclosure 'Goths and Vandals' (Gazley, 1973); John Smyth, a Gloucester landowner, said 'large commons and wastes burdened a village with beggarly cottages and idle people. They were better enclosed' (Thirsk, 1985); an Assistant Tithe Commissioner said that the heaths of Suffolk were 'mere sand encumbered with furze (*Ulex europeaus*) and fit for nothing but rabbits and sheepwalk' (Burrell, 1960); and Board of Agriculture reporters said common property resources were 'the trifling fruits of overstocked and ill-kept lands' (Humphries, 1990). But after enclosure poor farmers had to destock as fodder sources beyond their farms were no longer available and hay prices rose; and many farmers, given small plots of land in lieu of grazing rights, sold them to larger landowners, and 'the money was drank at the ale house' (Young, 1791, in Humphries, 1990). Generally those people living in diverse landscapes fared better than those in the monocropped cereal lands. Of the arable lands Cobbett said there were 'no hedges, no ditches, no commons, no grassy lanes … and the wretched labourer has not a stick of wood, and has not place for a pig or cow to graze. What a difference there is between the faces you see here, and the round, red faces that you see in the wealds and forests' (Cobbett, 1830). Extensification into uncultivated lands to improve aggregate food production should thus be treated with caution unless there has been full quantification of their economic value to poor people's livelihoods, and necessary steps taken to offset damage.

The success of intensification during the British agricultural revolution would appear to suggest three important strategies for agricultural development of resource-poor lands today:

1. reform of national and regional research, extension and planning to create a dialogue with farming households, with particular emphasis upon sensitive survey techniques to discover indigenous practices and the promotion of technology generation and adaptation by farmers themselves;
2. national and regional support to farmer-to-farmer extension mechanisms to increase the speed of diffusion;
3. adjustment of national pricing and subsidy policies to support the intensification of on-farm resources so as to increase productivity without damaging the natural resource base.

There do, however, remain many uncertainties. It is still unclear why delays of 100–200 years in diffusion occurred – particularly, what role did the invention of extension mechanisms play? It is also far from clear what role population increase played – did increasing population drive the need to increase food production, or did more people simply mean greater likelihood of passive diffusion? Most historical evidence of experimentation relates to larger tenant and landlord farmers – is this because only larger farmers can afford to take the risks attendant upon experiments and trials, or is the record biased because it is their documents that have survived to this day? To what extent, then, does the small farmer experiment? And lastly, to what extent did the benefits of intensification on resource-poor lands offset the damage caused by extensification and loss of common property resources? Answers to these and related questions would provide us with a more precise and better understanding of the invention, extension and adaptation processes underlying agricultural revolutions.

Past Successes

G. R. Conway

The Japanese have made the dwarfing of wheat an art. The wheat stalk seldom grows longer than 50 to 60 centimeters. The head is short but heavy. No matter how much manure is used, the plant will not grow taller; rather the length of the wheat head is increased. Even on the richest soils, the wheat plants never fall down.

US adviser to the Meiji government, 1873[1]

Without the Green Revolution, the numbers of poor and hungry today would be far greater. Thirty-five years ago, according to FAO, there were about 1 billion people in the developing countries who did not get enough to eat, equivalent to 50 per cent of the population, compared to the under 20 per cent today.[2] If the proportion had remained unchanged the hungry would be in excess of 2 billion – more than double the current number. The achievement of the Green Revolution was to deliver annual increases in food production which more than kept pace with population growth.

Many factors contributed to this success story, but of central importance was the application of modern science and technology to the task of getting crops to yield more. Cereal yields, total cereal production and total food production in the developing countries all more than doubled between 1960 and 1985. Over the same period their population grew by about 75 per cent. As a result, the average daily calorie supply in the developing countries increased by a quarter, from under 2000 calories per person in the early 1960s to about 2500 in the mid-80s, of which 1500 was provided by cereals (Figure 13.1).[3]

The history of the Green Revolution is well known, but is worth recounting here as a reminder of the power and limitations of innovative technology, and the crucial importance to its success of the economic, social and institutional environment within which it has to operate.

A careful analysis of the trends in agricultural productivity in a variety of countries, both developed and developing, suggests there is a point in history when yields begin to take off.[4] While agricultural production remains based on tradi-

tional practices, with fewer or no outside inputs, yield gains are modest, of the order of 1 per cent or less per annum. Production grows, barely perceptibly and largely as a result of increases in cropped area, until a critical threshold is reached when a transition to a new basis for production occurs. Much-improved varieties appear, farmers turn to inorganic fertilizers and synthetic pesticides, invest in irrigation and drainage and adopt a range of other new technologies, including the purchase of agricultural machinery.

From their analyses, Cornelius de Wit and his colleagues of the University of Wageningen in the Netherlands conclude this transition occurs when cereal yields reach about 1700kg/ha. Below the take-off point yield increases are of the order of 17kg/ha per year; afterwards they are 50–85kg/ha. There are, of course, exceptions: some countries (China is an example) experienced take-off from much lower yield levels, others, such as Britain and Japan, produced several spurts of growth with relatively low rates in between. Selection of indigenous rice varieties in Japan, coupled with increased irrigation, resulted in a yield increase between the 1880s and the First World War of about 40kg/ha per year.[5] Yields grew more slowly between the wars and then took off again after the Second World War, with annual yield growth of 75kg/ha per year.

In most developed countries the take-offs occurred soon after the end of the Second World War. High-yielding varieties, new fertilizer formulations and more effective pesticides came on the market, together with machinery that permitted more timely agricultural operations. Economic incentives, which included guaranteed prices, deficiency payments and other forms of subsidy, made sure the new technologies were widely adopted. Thereafter, growth in production was nearly entirely due to yield increase; in most developed countries the cropped area has declined since 1950.

The take-offs in the developing countries mostly occurred at the end of the 1960s as the new varieties produced by the Green Revolution began to be widely adopted. William Gaud, the administrator of USAID, first coined the name 'Green Revolution'.[6] At the time it was an appropriate description of a momentous event. Today 'Green' signifies the environment; then the image it conveyed was of a world covered with luxuriant and productive crops – the green swathes of young wheat- and ricefields. It was truly also a revolution in the scale of the transformation it achieved although, as we shall see, it did not go nearly far enough.

The origins of the revolution lay in a joint venture, the Office of Special Studies, established by the Mexican Ministry of Agriculture and the Rockefeller Foundation in 1943.[7] At the time, Mexican grain yields were very low, maize averaging about a quarter of US yields and wheat yielding less than 800kg/ha, even though most of the wheatland was irrigated. The Office was headed by George Harrar, with Edwin Wellhausen, a maize breeder, Norman Borlaug, a plant pathologist, and William Colwell, a soil scientist. Eventually the office was to have 21 US and 100 Mexican scientists, mostly working at an experiment station at Chapingo on the rain-fed central plateau. Its remit was to improve the yields of the basic food crops, maize, wheat and beans.

The research programme concentrated first on maize, the mainstay of the Mexican diet, consumed in the form of the thin, flat, unleavened bread called the tortilla. Mexican agronomists had already discovered that most strains of maize grown in the US were not well adapted to Mexican conditions, so the programme set out to try to duplicate the US achievement of breeding high-yielding, hybrid maizes but using indigenous varieties as a basis. Maize is a cross-pollinating crop, so that the seed collected by the farmer from his or her crop at the end of the season is usually highly variable. More uniform and higher-yielding hybrids can be created by deliberately crossing two distinct lines which have been inbred through several generations by self-pollination. The resulting hybrids combine the best features of both lines and usually have added a certain hybrid vigour.[8] At the time the Mexican programme began, about half of the cornland in the US was planted to hybrids. However, the disadvantage of hybrids is that new seed for each season has to be produced by repeating the cross, since the seed gathered at the end of the season from the hybrid crop will have lost the hybrid vigour and become contaminated. An alternative approach, adopted by Edwin Wellhausen, was to grow four or more inbred lines in an isolated field and let them cross naturally. These so-called 'synthetics' yielded better than the best existing varieties by 10–25 per cent and the farmers could simply save seed from their best plants from year to year.[9]

Success came very quickly. In 1948 1400 tons of seed of the improved maize varieties were planted. The new seed, good weather that season and the ready availability of fertilizer resulted in a record harvest and, for the first time since the revolution of 1910, Mexico had no need of imports. By the 1960s over one-third of Mexico's maizeland was being planted to new high-yielding varieties and maize yields were averaging over 1000kg per hectare. Total production had increased from 2 to 6 million tons.

Although maize was the main staple crop, Mexico was importing about a quarter of a million tons of wheat per year. Yields were very poor – 'most varieties were a hodge-podge of many different types, tall and short, bearded and beardless, early ripening and late ripening. Fields usually ripened so unevenly that it was impossible to harvest them at one time without losing too much over-ripe grain or including too much under-ripe grain in the harvest.'[10] In northern and central Mexico the soils had lost most of their fertility. On the newer, well-irrigated lands in the Pacific north-west the soil was generally fertile enough to produce high yields but stem rust was very destructive. Epidemics in three consecutive years, 1939–1941, in Sonora had caused many farmers to reduce their wheatland or stop growing the crop altogether.

The wheat programme, under the direction of Norman Borlaug, began by testing over 700 native and imported wheat varieties for rust resistance.[11] While some of the imported varieties were both more resistant to rust and higher yielding than the Mexican varieties, they had the disadvantage of late ripening. They needed the longer days of the northern summers to mature. But by crossing the imports with the best Mexican varieties, Borlaug produced, in 1949, four rust-resistant varieties each adapted to a particular ecological region of Mexico. Wheat is a self-pollinating crop, so that crosses have to be made by hand, but once made the new varieties will breed true and farmers can use their harvested seed for the next year's crop. By 1951 the new varieties were being grown on 70 per cent of the total wheatland and, five years later, Mexico was producing over a million tons of wheat, with an average national yield of 1300kg/ha. Imports of foreign wheat were no longer required.

The next step in the wheat programme was to improve yields through greater use of fertilizers. Experiments on properly irrigated soils showed that 140kg/ha of nitrogen raised yields more than fourfold. Even on rain-fed soils, yields more than doubled and the addition of phosphate produced five- or sixfold increases. But the traditional varieties had a tendency to grow tall and lodge, that is they fell down under the weight of the luxuriant green growth produced by the extra nutrient uptake, in effect making the grain liable to rot and be less harvestable. The breeders also recognized the need for non-shattering varieties that would hold the grains until they were ripe enough for mechanized harvesting and threshing. And wheats with better milling and baking quality were required, now that Mexico was relying solely on its own wheats and not blending with the stronger, imported varieties.

As the quotation at the beginning of this chapter testifies, short-strawed varieties had long existed in Japan. In 1935 the Japanese had produced a new dwarf, Norin 10, by crossing one of their traditional dwarfs with Mediterranean and Russian varieties imported from the US.[12] This was spotted by a US agricultural officer working in Japan in 1946 and seeds were sent to Washington State University. Initially the crosses with US wheats resulted in sterile offspring but then a fertile cross was made from which, ten years later, Orville Vogel, of the US Department of Agriculture (USDA), produced a new semi-dwarf variety called Gaines that yielded a world record of over 14 tons/ha.

Norman Borlaug heard of Vogel's work and in 1953 obtained some of his early breeding material to cross with traditional Mexican varieties. By growing two crops a year, a summer crop at Chapingo and a winter crop at a second experimental station in the state of Sonora, lying in the rich, irrigated plain of the Pacific northwest of Mexico, he produced, in record time, two new, superior dwarf-wheat varieties. These were adapted to a wide range of day-length and other environmental factors, and highly responsive to fertilizer applications (Figure 13.2). By 1966 the new varieties were yielding 7 tons/ha. A decade later, virtually all of Mexico's wheatland was under these varieties and the country's average yield was close to 3 tons/ha, having quadrupled since 1950 (Figure 13.3). By 1985 total production had increased to 5·5 million tons.

Following the success of the new wheat and maize varieties in Latin America, attention turned to the needs of Asia. Over much of Asia the staple diet was, and still is, rice. Unlike wheat, rice is mostly grown by smallholders (on farms of less than 3ha) for home consumption. In the 1950s, over 90 per cent of the rice produced in the world was grown in Asia; national yields averaged between 800 and 1900kg/ha.[13]

Early in this century, Japan, China and Taiwan had developed a number of new rice varieties which had led to significant increases in production, but the major impact on Asian rice yields came in the 1960s as a result of the skilful efforts of two groups of breeders, working in ignorance of each other, in China and the Philippines. The benefits of scientists being able to pursue clear goals in multidisciplinary teams had convinced those involved in the Mexican programme of the need to create purpose-built research institutes which would attract scientists of the highest calibre. In 1961 the International Rice Research Institute (IRRI) was established at Los Baños in the Philippine province of Luzon as a joint venture

between the Philippine government and the Ford and Rockefeller Foundations. This was the first of a family of new research institutes equipped with first-class laboratories and adjoining experimental plots located on good, irrigated land.[14] Excellent living conditions and international salaries added to the ability to attract the best scientists from around the world.

The Ford Foundation became a partner partly because its community development programme in India, started in 1951, had underlined the importance of agricultural research. The programme, largely run by social scientists, had assumed that improved technology was readily available and needed only a programme of vigorous education for it to be implemented. However, the village extension workers often proved inexperienced in agriculture and, more important, encouragement of increased fertilizer use turned out to be ineffective because the traditional cereal varieties lodged. Forrest Hill, an agricultural economist and vice-president of the foundation, concluded that the foundation had 'got the cart before the horse'. What was needed, he believed, was innovative agricultural research to support the extension work.

The first director of IRRI was Robert Chandler. He assembled a team of rice experts drawn from the US, India, Japan, Taiwan, Ceylon and the Philippines.[15] Experience in Mexico with the wheat programme and the knowledge already obtained from breeding programmes in India provided a blueprint for the new rices that were required (Box 13.1). A large collection of rice types was quickly

Box 13.1 *A blueprint for the new rice varieties*

A short, stiff stem (90–110cm), giving resistance to lodging

Erect, narrow leaves, resulting in increased efficiency of sunlight utilization

High tillering and a grain to straw ratio of 1:1, producing high fertilizer responsiveness

Time of flowering insensitive to day-length, giving flexibility in planting date and location

Early maturity (less than 130 days), giving increased output per hectare per day

Resistance to the most serious pests and diseases: stem borer and rice blast

Wide adaptability in Asia

Highly nutritious, with a high protein content and a better balance of amino acids

High palatability

Source: Stakman et al, 1967 (n. 7) and Barker et al, 1985 (n. 13) amassed at Los Baños and of the crosses made in 1962, a particularly promising combination was between the tall, vigorous variety Peta from Indonesia and Dee-geo-woo-gen, a short, stiff-strawed variety from Taiwan which contained a single recessive gene for dwarfing. In 1966 the new variety, named IR8, was released for commercial planting in the Philippines. It was immediately successful and, amid considerable publicity, was dubbed the 'miracle rice'.

In parallel with the work at IRRI a very similar breeding programme had been launched at the Academy of Agricultural Sciences in the Chinese province of Guandong.[16] Although this was only known much later, the Chinese and Philippine teams were using breeding material containing the same dwarfing gene – the Taiwanese variety Dee-geo-woo-gen had probably originated in southern China. In 1959 the Chinese produced their first successful cross, similar in many respects to IR8, and known as Guang-chai-ai. It was rapidly taken up in the province of Guandong and in Jiangsu, Hunan and Fujian. By 1965, a year prior to the release of IR8, it was being grown on 3·3 million hectares.

IR8 combined the seedling vigour of Peta with the short straw of Dee-geo-woo-gen. It was, like the new wheats bred in Mexico, highly responsive to fertilizer and essentially insensitive to photoperiod, maturing in 130 days. Under irrigation it yielded 9 tons/ha in the dry season and, on the IRRI farm, when continuously cultivated with a rapid turnaround between crops, produced average annual yields of over 20 tons/ha. In Asian regional trials it outyielded virtually all other varieties, producing from 5–10 tons/ha.

There was an immediate impact on Philippine rice production. By 1970, one and a half million hectares, or half of the Philippines' riceland, was planted to the new varieties and the yield take-off had occurred. The Philippines became self-sufficient in rice production in 1968 and 1969 for the first time in decades, although this was temporarily lost in the early 1970s owing to bad weather and disease outbreaks. A decade later, 75 per cent of the riceland was planted to the new varieties, average yields were over 2000kg/ha and rising at nearly 70kg/ha per year (Figure 13.4).

To begin with, the new varieties were distributed somewhat haphazardly. When IR8 was first released, farmers who turned up at IRRI could have 2kg of seed free, provided they left their name and address. The seed spread within a few months to over two-thirds of the provinces of the Philippines. Later, seed was distributed through government agencies and a newly formed Seed Growers Association, composed of private farmers who both grew and marketed the new seed. Standard Oil of New Jersey (ESSO) also established 400 agroservice centres in the Philippines to serve as marketing outlets not only for fertilizer but for seed, pesticides and farm implements.[17]

Two Mexican farm advisers working in El Salvador had hit on the idea of putting together in one package all the basic inputs a farmer would need to try out a new variety on a small patch of ground. The idea quickly spread to other countries and was tried on a massive scale in the Philippines, where a typical package contained 0·9kg of IR8 seed, 19kg of fertilizer and 2·7kg of insecticide. The packages were

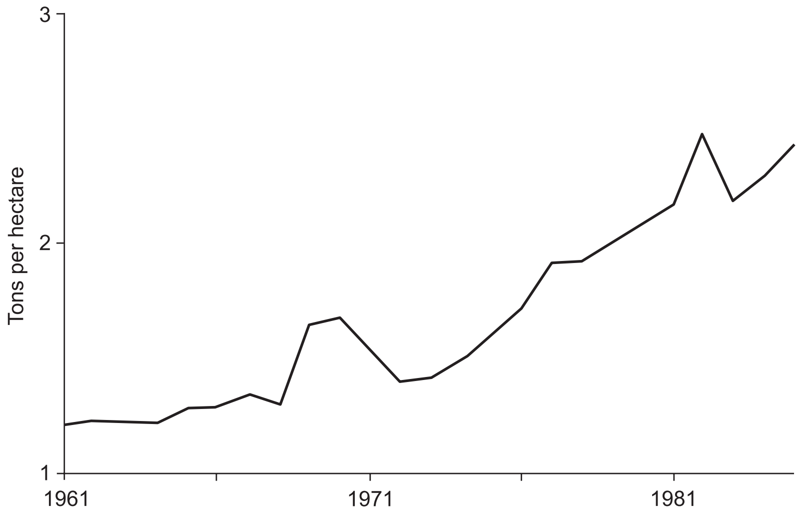

Figure 13.4 *Rice yields in the Philippines, 1961–1985*

produced by governments and also sold by fertilizer companies.[18] In addition to continuing its programme of food aid, the US aid agency, USAID, began to support fertilizer shipments in the 1960s and to finance rural infrastructure – farm-to-market roads, irrigation projects and rural electrification. It also funded a large force of technical assistance experts. Contracts were signed with US land-grant colleges to assist institution-building in education, research and extension and to create agricultural universities in the land-grant tradition. One of the most successful partnerships was between Cornell University and the University of the Philippines at Los Banos, next to the IRRI campus.

A conscious objective of the Green Revolution, from the beginning, was to produce varieties that could be grown in a wide range of conditions throughout the developing world. To meet this goal, the breeders in Mexico had successfully bred the new wheats to be photoperiod-insensitive, that is, they would flower and produce grain at any time of year, in contrast to traditional varieties which tend to flower at certain seasons, for example when the days are shortening. Provided the temperature was above a certain minimum and there was sufficient water, the new varieties would grow almost anywhere.

As early as the 1950s, successful trials of the new Mexican maize and wheat varieties were conducted in Latin America and Asia. The new varieties in India yielded at least a ton more than the local varieties. However, local pests and diseases and location-specific soil-management problems remained major constraints. And the importance of getting the package right was illustrated by an attempt to introduce the Mexican soft wheats to Tunisia, where the farmers are used to growing hard wheats, eaten in the form of couscous.[19] In the first year the trials gave average yields of 1·5 tons/ha, three times that of the hard wheat. The early maturity of the soft wheats also meant they could be harvested quickly before the drought set in. But the greatly expanded planting in the third year was a catastrophe, with yields of only 300kg/ha. The seed was of poor quality and, because of a complicated bureaucracy, was distributed too late. The farmers also planted it too deep for fear of drought and failed to keep the weeds down. In the fourth year they reverted to the traditional hard-wheat varieties.

To oversee the international effort, a wheat and maize improvement programme was established in 1966 under the umbrella of the International Centre for the Improvement of Maize and Wheat, located at Chapingo in Mexico and known by the initials (from its Spanish name) CIMMYT. The new seeds were mostly exported at a price very little above the world market price. In 1967–1968 Pakistan imported sufficient of the new wheat seeds to plant more than 400,000 hectares. Pakistan and India's yield take-offs occurred in 1967; subsequent yield increases were about 50kg/ha per year (Figure 13.5). A major impetus for the rapid uptake of the new varieties in South Asia was the two consecutive failures of the monsoon in 1966 and 1967. The US, which was the only country carrying food reserves of any size, had responded by shipping one-fifth of its grain crop to India.[20] This degree of dependence was recognized by both sides as being risky and undesirable. In some instances, food-aid agreements had permitted countries to put off serious agricultural development plans, and the large volume of food received had depressed prices and reduced the incentive for farmers to produce more. Then the monsoon failures helped to wipe out the world's surpluses and prices rose dramatically (rice going from \$120 to over \$200/ton in 1967). Faced with a food crisis of this magnitude, a number of developing-country leaders quickly recognized the potential of the new varieties. Presidents Ayub of Pakistan and Marcos of the Philippines and Prime Minister Demirel of Turkey took a personal and active part in the promotion of the Green Revolution, and were able to

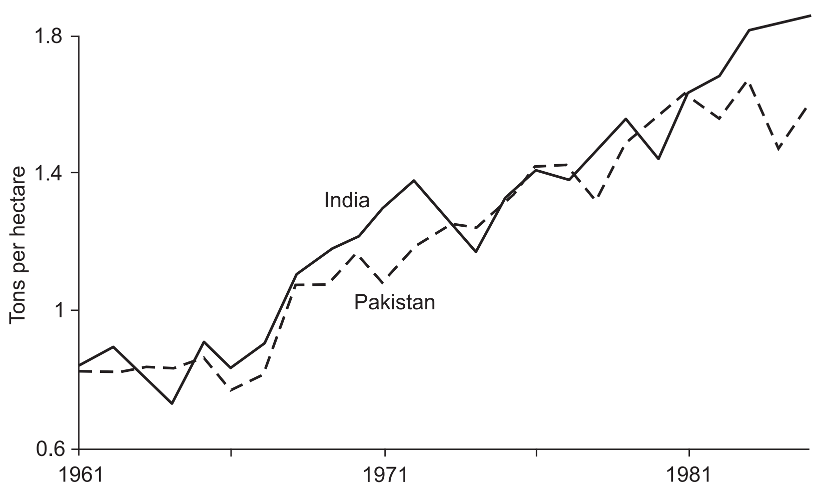

Figure 13.5 *Growth in wheat yields in India and Pakistan*

take some of the credit for its success. The re-election of President Marcos in 1969 owed much to the attainment of self-sufficiency in rice production.

The new wheats also proved popular in Argentina, where their early maturity made them appropriate for double-cropping with soybeans.[21] And in Egypt wheat yields took off in 1969, initially growing at over 60kg/ha per year but after 1980 at 200kg/ha.[22] The hybrid maizes were also successfully introduced into Egypt and into Kenya and Zimbabwe. However, the biggest impact came from their adoption in Latin America. To begin with this was slow because the traditional peasant farmers were reluctant to switch from the open-pollinated varieties which could be retained as seed on the farm for next year's harvest. However, by the early 1980s half the maize area of Latin America was sown to hybrids and yields had grown by a third since 1960. Chile, in particular, experienced dramatic growth, at over 200kg/ha per year after take-off in 1964. According to Donald Plucknett of the CGIAR this is the highest sustained growth rate that any cereal has so far experienced.[23] Average yields in 1985 were approaching 6 tons/ha.

The uptake of the new rice varieties was similarly dramatic. Twenty tons of IR8 seed were sent to India in 1966 and a further 5 tons to other Asian and Latin American countries. In Colombia it gave rise to a number of local variants developed by the Centre for Tropical Agriculture (Centro Internacional de Agricultura Tropical – CIAT) which soon replaced the indigenous varieties. By 1985 average yields were approaching 5 tons/ha and rice had become the dominant Colombian food crop.[24] Another remarkable transformation occurred in Indonesia, where oil revenues were used to finance the adoption of the new varieties and their accompanying packages. The take-off occurred in 1967, with subsequent rice-yield increases of over 100kg/ha (Figure 13.6).

Figure 13.6 *The growth of rice yields in Indonesia*

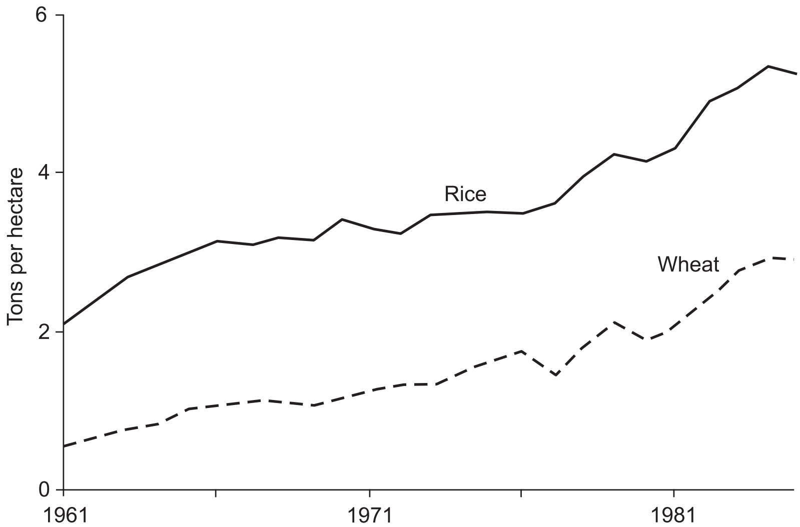

Figure 13.7 *Growth of rice and wheat yields in China*

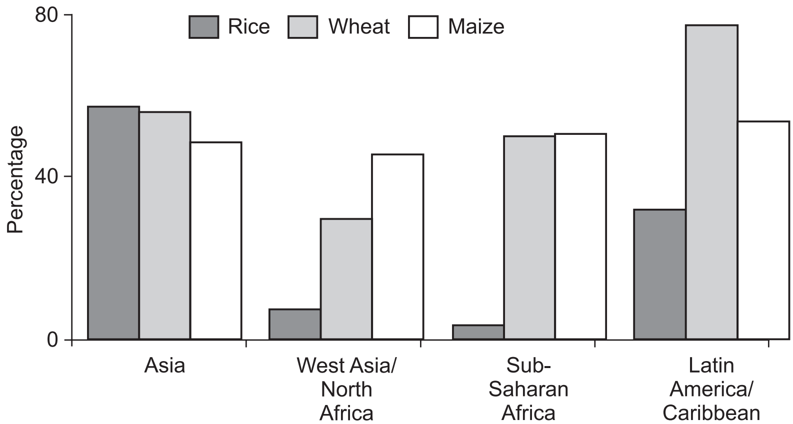
In China rice yields gained an extra boost from the development of hybrid rice. Rice, like wheat, is self-pollinating but the Chinese developed an inexpensive technique permitting cross-pollination on a large scale. The resulting hybrid rices have the same qualities of hybrid vigour as the hybrid maizes: yields are some 20 per cent, or about a ton, greater than the semi-dwarf rices. The first hybrid rice was distributed in 1974 and within a few years it was being planted on 15 per cent of Chinese riceland. China also introduced new high-yielding wheats from Mexico and crossed them with local varieties. Grain yields grew steadily in the 1970s and then accelerated after 1978, following the break-up of the communes, the re-establishment of the household as the unit of production and the encouragement of local markets (Figure 13.7).[25]

By the 1980s the Green Revolution and new Chinese varieties were dominating the grain lands of the developing world (Figure 13.8).[26]

Inevitably, there were many ‘teething problems’ in the early years. Governments were unprepared for the rapid rise in production. The land planted to IR8 in Pakistan increased a hundredfold, to over 400,000 hectares, in only a year. Storage, transport and marketing systems were sometimes overwhelmed. The 1968 Indian wheat harvest was one-third greater than the previous record and schools had to be closed in order to store the grain.[27] A huge harvest in Kalimantan, on the island of Borneo, went to waste because there was insufficient transport to get it to the centres of demand in Java. But these were the problems of success and they were quickly overcome.

Another early problem was the poor acceptability of some of the new varieties. Even poor, undernourished people retain a pride in eating good-quality grain. There was preference in India and Pakistan for chapatis made from the traditional



Source: M. Lipton and R. Longhurst, 1989, *New Seeds and Poor People*, London, Unwin Hyman

Figure 13.8 *Proportion of cereal lands under new Green Revolution or Chinese varieties in the early 1980s*

white grains rather than the reddish grains of the new varieties, but this problem was soon solved by breeding for white grain colour.[28] The grain of the first IRRI rices, such as IR8, was also rejected because it tended to harden excessively after cooking and farmers received a lower price than for the traditional grains. Quality improved with later varieties, but many farmers continued to prefer the traditional taste. In Indonesia the growing of traditional rice varieties was prohibited, a ban sometimes enforced by the destruction of crops in the fields. Farmers responded by cultivating the traditional rices in their home gardens or on the margins of fields growing the new varieties.

Other problems were more persistent and less amenable to simple solutions. They often required changes in government policies and the creation of new agencies. Inevitably the solutions created yet further problems. An example was the credit needs of the new technology. Adoption of the high-yielding packages was expensive: in Bangladesh the cost of the necessary inputs was 60 per cent more than for the traditional varieties. Small, subsistence farmers, often tenants or sharecroppers, could only afford the new packages if they borrowed from local moneylenders, invariably at high rates of interest. In the Philippines, where the majority of farmers are tenants, cash was borrowed from the landlords at rates of 60–90 per cent per annum, often producing a permanent state of indebtedness. The government response was to set up an Agricultural Guarantee Loan Fund, established at the Central Bank. This, in turn, supported numerous private rural banks which loaned without collateral and at reasonable interest rates. It was an important factor in determining the very rapid uptake of the new varieties in the Philippines.

However, there were drawbacks. Under the traditional feudal system, the tenants provided personal services for the landlord, gathering fuel or lending a hand with house repairs. In return, landlords helped with rice or money at times of economic hardship, providing a degree of protection against the outside world.[29] With the advent of the Green Revolution, this relationship became more commercial. Both sides benefited: yields on tenant farms rapidly increased as farmers gained from the landlord's better access to technical information, machinery and inputs. But the inputs had to be paid for and in bad years there was no longer any latitude. Credit repayments under the government scheme were due on schedule and defaulters were punished. The banks were less accommodating than the landlords.

Governments usually intervened directly to assure the supply of inputs. Demand for fertilizers grew rapidly in the early years, sometimes outstripping supply and forcing up prices.[30] The response was to fix prices and provide generous subsidies. Under the BIMAS programme in Indonesia, quotas were awarded to licensed importers, prices were fixed and distributors and retailers appointed right down to the cooperatives at village level. By the mid-1980s the subsidy for fertilizers had reached 68 per cent of the world price, for pesticides 40 per cent and for water nearly 90 per cent. Such high levels of subsidy created serious environmental problems. Also because the distribution of subsidized inputs tended to remain in the hands of government or quasi-government agencies, corruption became widespread and, in some situations, institutionalized. This has been most evident in government irrigation schemes.[31]

Pest and disease outbreaks have been an especially severe consequence of the Green Revolution.[32] In some cases the cause-and-effect relationship is simple. Pest populations have grown in response to higher nitrogen applications and diseases have become more prevalent in the microclimate created by the densely leaved, short-strawed wheats and rices. But often it is a combination of factors – higher nutrient levels, narrow genetic stock, uniform continuous planting and the misuse of pesticides – that have created conditions which encourage pest and disease attack.

According to some critics of the Green Revolution, the growth in production owed little to the new varieties, and was primarily due to agricultural expansion, arable cultivation moving on to increasingly marginal lands. But the evidence is otherwise: although area increases were important in the 1950s, the subsequent gains were largely derived from increasing yield per hectare. Other commentators claim the growth in production has been due to infrastructural and institutional change rather than the specific technical innovations, pointing to the lack of signs of the impact of the new varieties in the regional data.[33] But this is because the individual country take-offs, so clearly indicated in the graphs in this chapter, were staggered and hence are masked when aggregated together.

Nevertheless, the yield growth was not solely attributable to the new varieties. They were necessary but not sufficient alone for success. Their potential could only be realized if they were supplied with high quantities of fertilizer and provided with optimal supplies of water. As was soon apparent, the new varieties yielded better than the traditional at any level of fertilizer application, although

Figure 13.9 *The growth of fertilizer use in the developing countries*

without fertilizer they sometimes did worse on poor soils.[34] Not surprisingly, average rates of application of nitrogen fertilizers, mostly ammonium sulphate and urea, doubled and redoubled over a very short period (Figure 13.9).

Because the new varieties were more exacting in their requirements, good irrigation, by providing a controlled environment for growth, became crucial. Most developing countries have both a dry and a wet growing season. Potentially, dry-season yields are 50–100 per cent greater than in the wet, but the lack of rainfall in the dry season and the high evapotranspiration rates resulting from absence of cloud cover make the crops liable to water stress. Without adequate irrigation, yields tend to be low and variable, whatever the level of fertilizer application. With irrigation and heavy fertilizer application, some of the highest cereal yields in the world have been attained. In south and southeast Asia the irrigated area grew from some 40 million hectares to over 65 million hectares between 1960 and 1980, a growth rate of 2·2 per cent per annum. By 1980 one-third of the rice area was irrigated, producing a rapid increase in the dry-season rice crop.

Just how much of the increased cereal production has been due to the availability of the new varieties, how much to increased fertilizer use and how much to the growth of irrigation is a matter of argument. An analysis of the eight countries (Bangladesh, Burma, China, India, Indonesia, Philippines, Sri Lanka and Thailand) responsible for 85 per cent of the Asian rice crop suggested the three factors had a roughly equal contribution. Of the extra 117 million tons produced between 1965 and 1980, 27 million tons were attributable to the new varieties, 29 million tons to increased fertilizer use and 34 million tons to irrigation.[35]

Inevitably, the need to provide high levels of fertilizer and controlled, irrigated environments meant that some locations were favoured over others.

Uptake was fastest and most dramatic in those lands such as Sonora in Mexico, Luzon in the Philippines, the lowlands of Java, and the Punjab of India and Pakistan where irrigation was already well developed and where farmers, often larger than in the rest of the country, had good access to credit, had a greater propensity to take risks and were likely to be rapid adopters. Most important, innovation and adoption there was supported by governments willing and able to make and direct the necessary investments, including the necessary research structure which could take and adapt the new varieties to local conditions. These lands, scattered through Asia and Latin America, became the so-called Green Revolution lands.

In summary, the Green Revolution succeeded because it focused on three interrelated actions:

- breeding programmes for staple cereals to produce early-maturing, day-length-insensitive and high-yielding varieties;
- the organization and distribution of packages of high-pay-off inputs, such as fertilizers, pesticides and water regulation;
- implementation of these technical innovations in the most favourable agroclimatic regions and for those classes of farmers with the best expectations of realizing the potential yields.

In many ways this was a triumph for technology, rather than science. The dwarfing genes had been known for decades in China and Japan and most of the breeding techniques were well established. What made the difference was the investment, in China and independently in the rest of the developing world, in institutions and in the organization of delivery of the inputs necessary to make the science productive.

The success is undisputed, but it has been a revolution with serious limitations. In particular:

- its impact on the poor has been less than expected;
- it has not reduced, and in some cases it has encouraged, natural-resource degradation and environmental problems;
- its geographic impact has been localized; and
- there are signs of diminishing returns.

Soviet Collectivization, Capitalist Dreams

J. C. Scott

The master builders of Soviet society were rather more like Niemeyer designing Brasília than Baron Haussmann retrofitting Paris. A combination of defeat in war, economic collapse and a revolution had provided the closest thing to a bulldozed site that a state builder ever gets. The result was a kind of ultrahigh modernism that in its audacity recalled the Utopian aspects of its precursor, the French Revolution.

This is not the place, nor am I the most knowledgeable guide, for an extensive discussion of Soviet high modernism.[1] What I aim to do, instead, is to emphasize the cultural and aesthetic elements in Soviet high modernism. This will in turn pave the way for an examination of an illuminating point of direct contact between Soviet and American high modernism: the belief in huge, mechanized, industrial farms.

In certain vital respects, Soviet high modernism is not a sharp break from Russian absolutism. Ernest Gellner has argued that of the two facets of the Enlightenment – the one asserting the sovereignty of the individual and his interests, the other commending the rational authority of experts – it was the second that spoke to rulers who wanted their 'backward' states to catch up. The Enlightenment arrived in Central Europe, he concludes, as a 'centralizing rather than a liberating force'.[2]

Strong historical echoes of Leninist high modernism can thus be found in what Richard Stites calls the 'administrative utopianism' of the Russian czars and their advisers in the 18th and 19th centuries. This administrative utopianism found expression in a succession of schemes to organize the population (serfs, soldiers, workers, functionaries) into institutions 'based upon hierarchy, discipline, regimentation, strict order, rational planning, a geometrical environment, and a form of welfarism'.[3] Peter the Great's Saint Petersburg was the urban realization of this vision. The city was laid out according to a strict rectilinear and radial plan on completely new terrain. Its straight boulevards were, by design, twice as wide as the tallest building, which was, naturally, at the geometric centre of the city. The buildings themselves reflected function and hierarchy, as the façade, height and material of each corresponded to the social class of its inhabitants. The city's physical layout was in fact a legible map of its intended social structure.

Reprinted from Scott J C. 1998. Soviet collectivism, capitalist dreams, in *Seeing Like a State.* Yale University Press, New Haven, pp193–222.

Saint Petersburg had many counterparts, urban and rural. Under Catherine the Great, Prince Grigory Potemkin established a whole series of model cities (such as Ekaterinoslav) and model rural settlements. The next two czars, Paul and Alexander I, inherited Catherine's passion for Prussian order and efficiency.[4] Their adviser, Alexei Arakcheev, established a model estate on which peasants wore uniforms and followed elaborate instructions on upkeep and maintenance, to the point of carrying 'punishment books' inscribed with records of their violations. This estate was made the basis of a far bolder plan for a network of widely scattered, self-sufficient military colonies, which by the late 1820s included 750,000 people. This attempt to create a new Russia, in contrast to the disorder, mobility and flux of a frontier society, quickly succumbed to popular resistance, corruption and inefficiency. Long before the Bolsheviks took power, in any case, the historical landscape was littered with the wreckage of many miscarried experiments in authoritarian social planning.

Lenin and his confederates could implement their high-modernist plans starting from nearly zero. The war, the revolution and the subsequent famine had gone a long way toward dissolving the prerevolutionary society, particularly in the cities. A general collapse of industrial production had provoked a vast exodus from the cities and a virtual regression to a barter economy. The ensuing four-year civil war further dissolved existing social ties as well as schooling the hard-pressed Bolsheviks in the methods of 'war Communism' – requisitions, martial law, coercion.

Working on a levelled social terrain and harbouring high-modernist ambitions in keeping with the distinction of being the pioneers of the first socialist revolution, the Bolsheviks thought big. Nearly everything they planned was on a monumental scale, from cities and individual buildings (the Palace of Soviets) to construction projects (the White Sea Canal) and, later, the great industrial projects of the first Five-Year Plan (Magnitogorsk), not to mention collectivization. Sheila Fitzpatrick has appropriately called this passion for sheer size 'gigantomania'.[5] The economy itself was conceived as a well-ordered machine, where everyone would simply produce goods of the description and quantity specified by the central state's statistical bureau, as Lenin had foreseen.

A transformation of the physical world was not, however, the only item on the Bolshevik agenda. It was a cultural revolution that they sought, the creation of a new person. Members of the secular intelligentsia were the most devoted partisans of this aspect of the revolution. Campaigns to promote atheism and to suppress Christian rituals were pressed in the villages. New 'revolutionary' funeral and marriage ceremonies were invented amidst much fanfare, and a ritual of 'Octobering' was encouraged as an alternative to baptism.[6] Cremation – rational, clean, economical – was promoted. Along with this secularization came enormous and widely popular campaigns to promote education and literacy. Architects and social planners invented new communal living arrangements designed to supersede the bourgeois family pattern. Communal food, laundry and child-care services promised to free women from the traditional division of labour. Housing arrangements were explicitly intended to be 'social condensers'.

The 'new man' – the Bolshevik specialist, engineer or functionary – came to represent a new code of social ethics, which was sometimes simply called *kultura*. In keeping with the cult of technology and science, kultura emphasized punctuality, cleanliness, businesslike directness, polite modesty, and good, but never showy, manners.[7] It was this understanding of kultura and the party's passion for the League of Time, with its promotion of time consciousness, efficient work habits and clock-driven routine, that were so brilliantly caricatured in Eugene Zamiatin's novel *We* and that later became the inspiration for George Orwell's *1984*.

What strikes an outside observer of this revolution in culture and architecture is its emphasis on public form – on getting the visual and aesthetic dimensions of the new world straight. One can perhaps see this best in what Stites calls the 'festivals of mustering' organized by the cultural impresario of the early Soviet state, Anatoly Lunacharsky.[8] In the outdoor dramas he produced, the revolution was reenacted on a scale that must have seemed as large as the original, with cannons, bands, searchlights, ships on the river, 4000 actors and 35,000 spectators.[9] Whereas the actual revolution had all the usual messiness of reality, the reenactment called for military precision, and the various actors were organized by platoon and mobilized with semaphore and field telephones. Like mass exercises, the public spectacle gave a retroactive order, purpose and central direction to the events, which were designed to impress the spectator, not to reflect the historical facts.[10] If one can see in Arakcheev's military colonies an attempt to prefigure, to represent, a wished-for order, then perhaps Lunacharsky's staged revolution can be seen as a representation of the wished-for relationship between the Bolsheviks and the proletarian crowd. Little effort was spared to see that the ceremony turned out right. When Lunacharsky himself complained that churches were being demolished for the May Day celebrations, Lazar Kaganivich, the city boss of Moscow, replied, 'And *my* aesthetics demand that the demonstration processions from the six districts of Moscow should all pour into Red Square at the same time.'[11] In architecture, public manners, urban design and public ritual, the emphasis on a visible, rational, disciplined social facade seemed to prevail.[12] Stites suggests that there is some inverse relation between this public face of order and purpose and the near anarchy that reigned in society at large: 'As in the case of all such Utopias, its organizers described it in rational, symmetrical terms, in the mathematical language of planning, control figures, statistics, projections and precise commands. As in the vision of military colonies, which the Utopian plan faintly resembled, its rational facade barely obscured the oceans of misery, disorder, chaos, corruption and whimsicality that went with it.'[13]

One possible implication of Stites's assertion is that, in some circumstances, what I call the miniaturization of order may be substituted for the real thing. A facade or a small, easily managed zone of order and conformity may come to be an end in itself; the representation may usurp the reality. Miniatures and small experiments have, of course, an important role in studying larger phenomena. Model aircraft built to scale and wind tunnels are essential steps in the design of new airplanes. But when the two are confused – when, say, the general mistakes the parade ground for the battlefield itself – the consequences are potentially disastrous.

A Soviet-American Fetish: Industrial Farming

Before plunging into a discussion of the practice and logic of Soviet collectivization, we should recognize that the rationalization of farming on a huge, even national, scale was part of a faith shared by social engineers and agricultural planners throughout the world.[14] And they were conscious of being engaged in a common endeavour. Like the architects of the Congrès Internationaux d'Architecture Moderne, they kept in touch through journals, professional conferences and exhibitions. The connections were strongest between US agronomists and their Russian colleagues – connections that were not entirely broken even during the Cold War. Working in vastly different economic and political environments, the Russians tended to be envious of the level of capitalization, particularly in mechanization, of US farms while the Americans were envious of the political scope of Soviet planning. The degree to which they were working together to create a new world of large-scale, rational, industrial agriculture can be judged by this brief account of their relationship.

The high tide of enthusiasm for applying industrial methods to agriculture in the US stretched roughly from 1910 to the end of the 1930s. Agricultural engineers, a new specialty, were the main carriers of this enthusiasm; influenced by currents in their parent discipline, industrial engineering, and most particularly by the doctrines of the prophet of time–motion studies, Frederick Taylor, they reconceptualized the farm as a 'food and fiber factory'.[15] Taylorist principles of scientifically measuring work processes in order to break them down into simple, repetitive motions that an unskilled worker could learn quickly might work well enough on the factory floor,[16] but their application to the variegated and nonrepetitive requirements of growing crops was questionable. Agricultural engineers therefore turned to those aspects of farm operation that might be more easily standardized. They tried to rationalize the layout of farm buildings, to standardize machinery and tools, and to promote the mechanization of major grain crops.

The professional instincts of the agricultural engineers led them to try to replicate as much as possible the features of the modern factory. This impelled them to insist on enlarging the scale of the typical small farm so that it could mass-produce standard agricultural commodities, mechanize its operation, and thereby, it was thought, greatly reduce the unit cost of production.[17]

As we shall see later, the industrial model was applicable to some, but not all, of agriculture. It was nonetheless applied indiscriminately as a creed rather than a scientific hypothesis to be examined sceptically. The modernist confidence in huge scale, centralization of production, standardized mass commodities and mechanization was so hegemonic in the leading sector of industry that it became an article of faith that the same principles would work, *pari passu*, in agriculture.

Many efforts were made to put this faith to the test. Perhaps the most audacious was the Thomas Campbell 'farm' in Montana, begun – or, perhaps I should say, founded – in 1918.[18] It was an industrial farm in more than one respect. Shares were sold by prospectuses describing the enterprise as an 'industrial opportunity';

J. P. Morgan, the financier, helped to raise $2 million from the public. The Montana Farming Corporation was a monster wheat farm of 95,000 acres, much of it leased from four Native American tribes. Despite the private investment, the enterprise would never have gotten off the ground without help and subsidies from the Department of Interior and the USDA.

Proclaiming that farming was about 90 per cent engineering and only 10 per cent agriculture, Campbell set about standardizing as much of his operation as possible. He grew wheat and flax, two hardy crops that needed little if any attention between planting and harvest time.[19] The land he farmed was the agricultural equivalent of the bulldozed site of Brasília. It was virgin soil, with a natural fertility that would eliminate the need for fertilizer. The topography also vastly simplified matters: it was flat, with no forests, creeks, rocks or ridges that would impede the smooth course of machinery over its surface. In other words, the selection of the simplest, most standardized crops and the leasing of something very close to a blank agricultural space were calculated to favour the application of industrial methods. In the first year Campbell bought 33 tractors, 40 binders, 10 threshing machines, 4 combines and 100 wagons; he employed about 50 men most of the year, but hired as many as 200 during the peak season.[20]

This is not the place to chronicle the fortunes of the Montana Farming Corporation, and in any event Deborah Fitzgerald has done so splendidly.[21] Suffice it to note that a drought in the second year and the elimination of government support for prices the following year led to a collapse that cost J. P. Morgan $1 million. The Campbell farm faced other problems besides weather and prices: soil differences, labour turnover, the difficulty of finding skilled, resourceful workers who would need little supervision. Although the corporation struggled on until Campbell's death in 1966, it provided no evidence that industrial farms were superior to family farms in efficiency and profitability. The advantages industrial farms did have over smaller producers were of another kind. Their very size gave them an edge in access to credit, political influence (relevant to taxes, support payments and the avoidance of foreclosure) and marketing muscle. What they gave away in agility and quality labour they often made up for in their considerable political and economic clout.

Many large industrial farms managed along scientific lines were established in the 1920s and 1930s.[22] Some of them were the stepchildren of depression foreclosures that left banks and insurance companies holding many farms they could not sell. Such 'chain farms', consisting of as many as 600 farmsteads organized into one integrated operation (one farm to farrow pigs, say, and another to feed them out, along the lines of contemporary 'contract farming' for poultry), were quite common, and buying into them was a speculative investment.[23] They proved no more competitive to the family farm than did Campbell's corporation. In fact, they were so highly capitalized that they were vulnerable to unfavourable credit markets and lower farm gate prices, given their high fixed costs in payroll and interest. The family farm could, by contrast, more easily tighten its belt and move into a subsistence mode.

The most striking proposal designed to reconcile the American small-property regime with huge economies of scale and scientific, centralized management was that of Mordecai Ezekial and Sherman Johnson in 1930. They outlined a 'national farming corporation' that would incorporate all farms. It would be vertically integrated and centralized and 'could move raw farming materials through the individual farms of the country, could establish production goals and quotas, distribute machinery, labor and capital, and move farm products from one region to another for processing and use. Bearing a striking resemblance to the industrial world, this organizational plan was a sort of gigantic conveyor belt'.[24] Ezekial was no doubt influenced by his recent tour of Russian collective farms as well as by the plight of the depression-stricken economy. Johnson and Ezekial were hardly alone in calling for centralized industrial farming on a massive scale, not just as a response to economic crisis but as a matter of confidence in an ineluctable high-modernist future. The following expression of that confidence is fairly representative: 'Collectivization is posed by history and economics. Politically, the small farmer or peasant is a drag on progress. Technically, he is as antiquated as the small machinists who once put automobiles together by hand in little wooden sheds. The Russians have been the first to see this clearly, and to adapt themselves to historical necessity.'[25]

Behind these admiring references to Russia was less a specifically political ideology than a shared high-modernist faith. That faith was reinforced by something on the order of an improvised, high-modernist exchange programme. A great many Russian agronomists and engineers came to the US, which they regarded as the Mecca of industrial farming. Their tour of US agriculture nearly always included a visit to Campbell's Montana Farming Corporation and to M. L. Wilson, who in 1928 headed the Department of Agricultural Economics at Montana State University and later became a high-level official in the Department of Agriculture under Henry Wallace. The Russians were so taken with Campbell's farm that they said they would provide him with 1 million acres if he would come to the Soviet Union and demonstrate his farming methods.[26]

Traffic in the other direction was just as brisk. The Soviet Union had hired thousands of US technicians and engineers to help in the design of various elements of Soviet industrial production, including the production of tractors and other farm machinery. By 1927, the Soviet Union had also purchased 27,000 American tractors. Many of the American visitors, such as Ezekial, admired Soviet state farms, which by 1930 offered the promise of collectivized agriculture on a massive scale. The Americans were impressed not just by the sheer size of the state farms but also by the fact that technical specialists – agronomists, economists, engineers, statisticians – were, it seemed, developing Russian production along rational, egalitarian lines. The failure of the Western market economy in 1930 reinforced the attractiveness of the Soviet experiment. Visitors travelling in either direction returned to their own country thinking that they had seen the future.[27]

As Deborah Fitzgerald and Lewis Feuer argue, the attraction that collectivization held for American agricultural modernizers had little to do with a belief in

Marxism or an affinity for Soviet life.[28] 'Rather it was because the Soviet idea of growing wheat on an industrial scale and in an industrial fashion was similar to US ideas about the direction American agriculture should take.'[29] Soviet collectivization represented, to these American viewers, an enormous demonstration project without the political inconveniences of American institutions; 'that is, the Americans viewed the giant Soviet farms as huge experiment stations on which Americans could try out their most radical ideas for increasing agricultural production, and, in particular, wheat production. Many of the things they wished to learn more about simply could not be tried in America, partly because it would cost too much, partly because no suitable large farmsite was available, and partly because many farmers and farm laborers would be alarmed at the implications of this experimentation.'[30] The hope was that the Soviet experiment would be to American industrial agronomy more or less what the Tennessee Valley Authority was to be to American regional planning: a proving ground and a possible model for adoption.

Although Campbell did not accept the Soviet offer of a vast demonstration farm, others did. M. L. Wilson, Harold Ware (who had extensive experience in the Soviet Union), and Guy Riggin were invited to plan a huge mechanized wheat farm of some 500,000 acres of virgin land. It would be, Wilson wrote to a friend, the largest mechanized wheat farm in the world. They planned the entire farm layout, labour force, machinery needs, crop rotations and lockstep work schedule in a Chicago hotel room in two weeks in December 1928.[31] The fact that they imagined that such a farm *could* be planned in a Chicago hotel room underlines their presumption that the key issues were abstract, technical interrelationships that were context-free. As Fitzgerald perceptively explains: 'Even in the U.S., those plans would have been optimistic, actually, because they were based on an unrealistic idealization of nature and human behavior. And insofar as the plans represented what the Americans would do if they had millions of acres of flat land, lots of laborers, and a government commitment to spare no expense in meeting production goals, *the plans were designed for an abstract, theoretical kind of place*. This agricultural place, which did not correspond to America, Russia, or any other actual location, obeyed the laws of physics and chemistry, recognized no political or ideological stance.'[32]

The giant *sovkhoz*, named Verblud, which they established near Rostov-on-Don, one thousand miles south of Moscow, comprised 375,000 acres that were to be sown to wheat. As an economic proposition, it was an abject failure, although in the early years it did produce large quantities of wheat. The detailed reasons for the failure are of less interest for our purposes than the fact that most of them could be summarized under the rubric of *context*. It was the specific context of this specific farm that defeated them. The farm, unlike the plan, was not a hypothecated, generic, abstract farm but an unpredictable, complex and particular farm, with its own unique combination of soils, social structure, administrative culture, weather, political strictures, machinery, roads and the work skills and habits of its employees. As we shall see, it resembled Brasília in being the kind of failure typical of ambitious high-modernist schemes for which local knowledge practice, and context are considered irrelevant or at best an annoyance to be circumvented.

Collectivization in Soviet Russia

> *What we have here isn't a mechanism, it's people living here. You can't get them squared around until they get themselves arranged. I used to think of the revolution as a steam engine, but now I see that it's not.*
>
> Andrei Platonov, *Chevengur*

The collectivization of Soviet agriculture was an extreme but diagnostic case of authoritarian high-modernist planning. It represented an unprecedented transformation of agrarian life and production, and it was imposed by all the brute force at the state's disposal. The officials who directed this massive change, moreover, were operating in relative ignorance of the ecological, social and economic arrangements that underwrote the rural economy. They were flying blind.

Between early 1930 and 1934, the Soviet state waged a virtual war in the countryside. Realizing that he could not depend on the rural Soviets to 'liquidate the *kulaks*' and collectivize, Stalin dispatched 25,000 battle-tested, urban Communists and proletarians with full powers to requisition grain, arrest resistors and collectivize. He was convinced that the peasantry was trying to bring down the Soviet state. In reply to a personal letter from Mikhail Sholokhov (author of *And Quiet Flows the Don*) alerting him to the fact that peasants along the Don were on the verge of starvation, Stalin replied, 'The esteemed grain growers of your district (and not only of your district alone) carried on an "Italian strike" (*ital'ianka*), sabotage!, and were not loathe to leave the workers and the Red Army without bread. That the sabotage was quiet and outwardly harmless (without bloodshed) does not change the fact that the esteemed grain growers waged what was virtually a "quiet" war against Soviet power. A war of starvation, dear comrade Sholokhov.'[33]

The human costs of that war are still in dispute, but they were undeniably grievous. Estimates of the death toll alone, as a result of the 'dekulakization' and collectivization campaigns and the ensuing famine, range from a 'modest' 3 or 4 million to, as some current Soviet figures indicate, more than 20 million. The higher estimates have, if anything, gained more credibility as new archival material has become available. Behind the deaths rose a level of social disruption and violence that often exceeded that of the civil war immediately following the revolution. Millions fled to the cities or to the frontier, the infamous gulag was vastly enlarged, open rebellion and famine raged in much of the countryside, and more than half of the nation's livestock (and draft power) was slaughtered.[34]

By 1934, the state had 'won' its war with the peasantry. If ever a war earned the designation 'Pyrrhic victory', this is the one. The *sovkhoz* (state farms) and *kolkhoz* (collective farms) failed to deliver on any of the specifically socialist goals envisioned by Lenin, Trotsky, Stalin and most Bolsheviks. They were an evident failure in raising the level of grain production or of producing cheap and abundant foodstuffs for an urban, industrializing workforce. They failed to become the technically efficient and innovative farms that Lenin had anticipated. Even in the realm of electrification, Lenin's touchstone of modernization, only 1 in 25 collective farms had electricity by the eve of World War II. By no measure had the collectivization of agriculture created 'new men and women' in the countryside or abolished the cultural difference between the country and the city. For the next half-century, the yields per hectare of many crops were stagnant or actually inferior to the levels recorded in the 1920s or the levels reached before the Revolution.[35]

At another level, collectivization was, in a curious state-centric way, a qualified success. Collectivization proved a rough-and-ready instrument for the twin goals of traditional statecraft: appropriation and political control. Though the Soviet kolkhoz may have failed badly at generating huge surpluses of foodstuffs, it served well enough as a means whereby the state could determine cropping patterns, fix real rural wages, appropriate a large share of whatever grain was produced, and politically emasculate the countryside.[36]

The great achievement, if one can call it that, of the Soviet state in the agricultural sector was to take a social and economic terrain singularly unfavourable to appropriation and control and to create institutional forms and production units far better adapted to monitoring, managing, appropriating and controlling from above. The rural society that the Soviet state inherited (and for a time encouraged) was one in which the allies of the czarist state, the great landlords and the aristocratic officeholders, had been swept away and been replaced by smallholding and middle peasants, artisans, private traders and all sorts of mobile labourers and lumpen elements.[37] Confronting a tumultuous, footloose and 'headless' (acephalous) rural society which was hard to control and which had few political assets, the Bolsheviks, like the scientific foresters, set about redesigning their environment with a few simple goals in mind. They created, in place of what they had inherited, a new landscape of large, hierarchical, state-managed farms whose cropping patterns and procurement quotas were centrally mandated and whose population was, by law, immobile. The system thus devised served for nearly 60 years as a mechanism for procurement and control at a massive cost in stagnation, waste, demoralization and ecological failure.

That collectivized agriculture persisted for 60 years was a tribute less to the plan of the state than to the improvisations, grey markets, bartering and ingenuity that partly compensated for its failures. Just as an 'informal Brasília', which had no legitimate place in official plans, arose to make the city viable, so did a set of informal practices lying outside the formal command economy – and often outside Soviet law as well – arise to circumvent some of the colossal waste and inefficiencies built into the system. Collectivized agriculture, in other words, never quite operated according to the hierarchical grid of its production plans and procurements.

What seems clear, in the brief account that follows, is that collectivization per se cannot be laid solely at the feet of Stalin, though he bore much responsibility for its exceptional speed and brutality.[38] A collectivized agriculture was always part of the Bolshevik map of the future, and the great procurement struggles of the late 1920s could hardly have had any other outcome in the context of the decision to pursue forced-draft industrialization. The party's high-modernist faith in great collectivist schemes survived long after the desperate improvisations of the early 1930s. That faith, which claimed to be both aesthetic and scientific, is clearly visible in a much later agrarian high-modernist dream: namely, Khrushchev's virgin lands scheme, launched well after Stalin's death and after his crimes during collectivization had been publicly denounced. What is remarkable is how long these beliefs and structures prevailed, in spite of the evidence of their manifold failings.

Round one: The Bolshevik state and the peasantry

> *It sometimes seems to me that if I could persuade everyone to say 'systematize' each time he wanted to say 'liberate' and to say 'mobilization' every time he wanted to say 'reform' or 'progress' I would not have to write long books about government–peasant interaction in Russia.*
>
> George Yaney, *The Urge to Mobilize*

In the particular book quoted above, Yaney was writing about pre-revolutionary Russia, but he could just as easily have been writing about the Bolshevik state. Until 1930, the continuities between the rural policy of the Leninist state and its czarist predecessor are more striking than their differences. There is the same belief in reform from above and in large, modern, mechanized farms as the key to productive agriculture. There is also, alas, the same high level of ignorance about a very complex rural economy coupled, disastrously, with heavy-handed raids on the countryside to seize grain by force. Although the continuities persisted even after the institutional revolution of 1930, what is new about the all-out drive to collectivize is the revolutionary state's willingness to completely remake the institutional landscape of the agrarian sector, and at whatever cost.

The new Bolshevik state faced a rural society that was significantly more opaque, resistant, autonomous and hostile than the one encountered by the czarist bureaucracy. If the czarist officials had provoked massive defiance and evasion in their 'crude Muscovite tribute-collecting methods' during World War I,[39] there was every reason to suspect that the Bolsheviks would have an even harder time squeezing grain from the countryside.

If much of the countryside was hostile to the Bolsheviks, the sentiment was abundantly reciprocated. For Lenin, as we have seen, the Land Decree, which gave to the peasants the land that they had seized, had been a strategic manoeuvre designed to buy rural quiescence while power was consolidated; he had no doubt that peasant smallholdings must eventually be abolished in favour of large, socialized farms. For Trotsky, the sooner what he called 'the Russia of icons and cockroaches' was transformed and 'urbanized', the better. And for many of the newly urbanized, rank-and-file Bolsheviks, the abolition of the 'dark and backward peasant world' was a 'vital part of their own emerging personal and working-class identity'.[40]

The peasantry was virtually terra incognita to the Bolsheviks. At the time of the revolution, the party had throughout Russia a grand total of 494 'peasant' members (most of them probably rural intelligentsia).[41] Most villagers had never seen a Communist, although they may well have heard of the Bolshevik decree confirming peasant ownership of the land that had been seized. The only revolutionary party with any rural following was the Social Revolutionaries, whose populist roots tended to make them unsympathetic to Lenin's authoritarian outlook.

The effects of the revolutionary process itself had rendered rural society more opaque and hence more difficult to tax. There had already been a sweeping seizure of land, dignified, retrospectively, by the inappropriate term 'land reform'. In fact, after the collapse of the offensive into Austria during the war and the subsequent mass desertions, much of the land of the gentry and church, as well as 'crown land', had been absorbed by the peasantry. Rich peasants cultivating independent farmsteads (the 'separators' of the Stolypin reforms) were typically forced back into the village allotments, and rural society was in effect radically compressed. The very rich had been dispossessed, and many of the very poor became smallholders for the first time in their lives. According to one set of figures, the number of landless rural labourers in Russia dropped by half, and the average peasant holding increased by 20 per cent (in the Ukraine, by 100 per cent). A total of 248 million acres was confiscated, almost always by local initiative, from large and small landlords and added to peasant holdings, which now averaged about 70 acres per household.[42]

From the perspective of a tax official or a military procurement unit, the situation was nearly unfathomable. The land-tenure status in each village had changed dramatically. Prior landholding records, if they existed at all, were entirely unreliable as a guide to current land claims. Each village was unique in many respects, and, even if it could in principle have been 'mapped', the population's mobility and military turmoil of the period all but guaranteed that the map would have been made obsolete in six months or sooner. The combination, then, of smallholdings, communal tenure and constant change, both spatial and temporal, operated as an impenetrable barrier to any finely tuned tax system.

Two additional consequences of the revolution in the countryside compounded the difficulties of state officials. Before 1917, large peasant farms and landlord enterprises had produced nearly three-quarters of the grain marketed for domestic use and export. It was this sector of the rural economy that had fed the cities. Now it was gone. The bulk of the remaining cultivators were consuming a much larger share of their own yield. They would not surrender this grain without a fight. The new, more egalitarian distribution of land meant that extracting anything like the czarist 'take' in grain would bring the Bolsheviks in conflict with the subsistence needs of small and middle peasants.[43]

The second and perhaps decisive consequence of the revolution was that it had greatly enhanced the determination and capacity of peasant communities to resist the state. Every revolution creates a temporary power vacuum when the power of the ancien regime has been destroyed but the revolutionary regime has not yet asserted itself throughout the territory. Inasmuch as the Bolsheviks were largely urban and found themselves fighting an extended civil war, the power vacuum in much of the countryside was unusually pronounced. It was the first time, as Orlando Figes reminds us, that the villages, although in straitened circumstances, were free to organize their own affairs.[44] As we have seen, the villagers typically forced out or burned out the gentry, seized the land (including rights to common land and forests), and forced the separators back into the communes. The villages tended to behave as autonomous republics, well disposed to the Reds as long as they confirmed the local 'revolution', but strongly resistant to forced levies of grain, livestock or men from any quarter. In this situation, the fledgling Bolshevik state, arriving as it often did in the form of military plunder, must have been experienced by the peasantry as a reconquest of the countryside by the state – as a brand of colonization that threatened their newly won autonomy.

Given the political atmosphere in rural Russia, even a government having detailed knowledge of the agricultural economy, a local base of support, and a knack for diplomatic tact would have confronted great difficulties. The Bolsheviks lacked all three. A tax system based on income or wealth was possible only with a valid cadastral map and an up-to-date census, neither of which existed. Farm income, moreover, varied greatly with regard to yields and prices from year to year, so any income tax would have had to have been exceptionally sensitive to these conditions in local harvests. Not only did the new state lack the basic information it needed to govern efficiently, it had also largely destroyed the czarist state apparatus of local officials, gentry and specialists in finance and agronomy who had managed, however inadequately, to collect taxes and grain during the war. Above all, the Bolsheviks generally lacked the village-level native trackers who could have helped them to find their way in a hostile and confusing environment. The village Soviets that were supposed to play this role were typically headed by villagers loyal to local interests rather than to the centre. An alternative organ, the Committee of the Rural Poor (*kombedy*), which purported to represent the rural proletariat in local class struggles, was either successfully coopted by the village or locked in often violent conflict with the village soviet.[45]

The inscrutability of the mir to most Bolshevik officials was not simply a result of their urban social origins and the admitted complexity of village affairs. It was also the product of a conscious local strategy, one that had demonstrated its protective value in earlier conflicts with the gentry and the state. The local commune had a long history of underreporting its arable land and overreporting its population in order to appear as poor and untaxable as possible.[46] As a result of such deception in the census of 1917, the arable land in Russia had been underestimated by about 15 per cent. Now, in addition to the woodland, pastures and open land that the peasantry had earlier converted into cropland without reporting it, they had an interest in hiding much of the land they had just seized from the landlords and the gentry. Village committees did, of course, keep records for allocating allotment land, organizing communal plough teams, fixing grazing schedules, and so on, but none of these records was made available either to officials or to the kombedy. A popular saying of the period captures the situation nicely: the peasant 'owned by decree' (that is, the Land Decree) but 'lived secretly'.

How did the hard-pressed state find its way in this labyrinth? Where possible, the Bolsheviks did try to establish large state farms or collective farms. Many of these were 'Potemkin collectives' designed merely to give cover of legitimacy to existing practices. But where they were not a sham, they revealed the political and administrative attractiveness of a radical simplification of the landholding and tax-paying unit in the countryside. Yaney's summary of the logic entailed is impeccable.

> From a technical point of view it was infinitely easier to plough up large units of land without regard for individual claims than it was to identify each family allotment, measure its value in the peasants' traditional terms, and then painfully transpose it from scattered strips into a consolidated farm. Then, too, a capital city administrator could not help but prefer to supervise and tax large productive units and not have to deal with separate farmers… The collective had a dual appeal to authentic agrarian reformers. They represented a social ideal for rhetorical purposes, and at the same time they seemed to simplify the technical problems of land reform and state control.[47]

In the turmoil of 1917–1921, not many such agrarian experiments were possible, and those that were attempted generally failed badly. They were, however, a straw in the wind for the full collectivization campaign a decade later.

Unable to remake the rural landscape, the Bolsheviks turned to the same methods of forced tribute under martial law that had been used by their czarist predecessors during the war. The term 'martial law', however, conveys an orderliness that was absent from actual practice. Armed bands (*otriady*) – some authorized and others formed spontaneously by hungry townsmen – plundered the countryside during the grain crisis of spring and summer 1918, securing whatever they could. Insofar as grain procurement quotas were set at all, they were 'purely mechanical accounting figures originating from an unreliable estimate of arable and assuming a good harvest'. They were, from the beginning, 'fictional and unfulfillable'.[48] The procurement of grain looked more like plunder and theft than delivery and purchase. Over 150 distinct uprisings, by one estimate, erupted against the state's grain seizures. Since the Bolsheviks had, in March 1918, renamed themselves the Communist Party, many of the rebels claimed to be for the Bolsheviks and the Soviets (whom they associated with the Land Decree) and against the Communists. Lenin, referring to the peasant uprisings in Tambov, the Volga and the Ukraine, declared that they posed more of a threat than all the Whites put together. Desperate peasant resistance had in fact all but starved the cities out of existence,[49] and in early 1921, the party, for the first time, turned its guns on its own rebellious sailors and workers in Kronstadt. At this point the beleaguered party beat a tactical retreat, abandoning War Communism and inaugurating the New Economic Policy (NEP), which condoned free trade and small property. As Figes notes, 'Having defeated the White Army, backed by eight Western powers, the Bolshevik government surrendered before its own peasants.'[50] It was a hollow victory. The deaths from the hunger and epidemics of 1921–1922 nearly equalled the toll claimed by World War I and the civil war combined.

Round two: High modernism and procurement

The conjunction of a high-modernist faith in what agriculture should look like in the future and a more immediate crisis of state appropriation helped to spark the all-out drive to collectivization in the winter of 1929–1930. In focusing on just these two issues, we must necessarily leave to others (and they are a multitude) the gripping issues of the human costs of collectivization, the struggle with the 'right' opposition led by Bukharin, and whether Stalin intended to liquidate Ukrainian culture as well as many Ukrainians.

There is no doubt that Stalin shared Lenin's faith in industrial agriculture. The aim of collectivization, he said in May 1928, was 'to transfer from small, backward, and fragmented peasant farms to consolidated, big, public farms, provided with machines, equipped with the data of science, and capable of producing the greatest quantity of grain for the market'.[51]

This dream had been deferred in 1921. There had been some hope that a gradually expanding collective sector in the 1920s could provide as much as one-third of the country's grain needs. Instead, the collectivized sector (both the state farms and the collective farms), which absorbed 10 per cent of the labour force, produced a dismal 2.2 per cent of gross farm production.[52] When Stalin decided on a crash industrialization programme, it was clear that the existing socialist agricultural sector could not provide either the food for a rapidly growing urban workforce or the grain exports necessary to finance the imported technology needed for industrial growth. The middle and rich peasants, many of them newly prosperous since the New Economic Policy, had the grain he needed.

Beginning in 1928, the official requisition policy put the state on a collision course with the peasantry. The mandated delivery price of grain was one-fifth of the market price, and the regime returned to using police methods as peasant resistance stiffened.[53] When the procurements faltered, those who refused to deliver what was required (who, along with anyone else opposing collectivization, were called kulaks, regardless of their economic standing) were arrested for deportation or execution, and all their grain, equipment, land and livestock were seized and sold. The orders sent to those directly in charge of grain procurement specified that they were to arrange meetings of poor peasants to make it seem as if the initiative had come from below. It was in the context of this war over grain, and not as a carefully planned policy initiative, that the decision to force 'total' (*sploshnaia*) collectivization was made in late 1929. Scholars who agree on little else are in accord on this point: the overriding purpose of collectivization was to ensure the seizure of grain. Fitzpatrick begins her study of the collectives with this assertion: 'The main purpose of collectivization was to increase state grain procurements and reduce the peasants' ability to withhold grain from the market. This purpose was obvious to peasants from the start, since the collectivization drive of the winter of 1929–1930 was the culmination of more than two years of bitter struggle between the peasants and the state over grain procurements.'[54] Robert Conquest concurs: 'The collective farms were essentially a chosen mechanism for extracting grain and other products.'[55]

It appears that this was also how the vast majority of the peasantry saw it, judging from their determined resistance and what we know of their views. The seizure of grain threatened their survival. The peasant depicted in Andrei Platonov's novel about collectivization sees how the seizure of grain negates the earlier land reform: 'It's a sly business. First you hand over the land, and then you take away the grain, right down to the last kernel. You can choke on land like that! The muzhik doesn't have anything left from the land except the horizon. Who are you fooling?'[56] At least as threatening was the loss of what little margin of social and economic autonomy the peasantry had achieved since the revolution. Even poor peasants were afraid of collectivization, because 'it would involve giving up one's land and implements and working with other families, under orders, not temporarily, as in the army, but forever – it means the barracks for life.'[57] Unable to rely on any significant rural support, Stalin dispatched 25,000 'plenipotentiaries' (party members) from the towns and factories 'to destroy the peasant commune and replace it by a collective economy subordinate to the state', whatever the cost.[58]

Authoritarian high-modernist theory and the practice of serfdom

If the move to 'total' collectivization was directly animated by the party's determination to seize the land and the crops sown on it once and for all, it was a determination filtered through a high-modernist lens. Although the Bolsheviks might disagree about means, they did think they knew exactly what modern agriculture should look like in the end; their understanding was as much visual as scientific. Modern agriculture was to be large in scale, the larger the better; it was to be highly mechanized and run hierarchically along scientific, Taylorist principles. Above all, the cultivators were to resemble a highly skilled and disciplined proletariat, not a peasantry. Stalin himself, before practical failures discredited a faith in colossal projects, favoured collective farms ('grain factories') of 125,000 to 250,000 acres, as in the American-assisted scheme described earlier.[59]

The Utopian abstraction of the vision was matched, on the ground, by wildly unrealistic planning. Given a map and a few assumptions about scale and mechanization, a specialist could devise a plan with little reference to local knowledge and conditions. A visiting agricultural official wrote back to Moscow from the Urals in March 1930 to complain that, 'on the instruction of the Raion Executive

Committee, twelve agronomists have been sitting for twenty days composing an operational-production plan for the non-existent raion commune without ever leaving their offices or going out into the field'.[60] When another bureaucratic monstrosity in Velikie Lukie in the west proved unwieldy, the planners simply reduced the scale without sacrificing abstraction. They divided the 80,000-hectare scheme into 32 equal squares of 2500 hectares each, with one square constituting a kolkhoz. 'The squares were drawn on a map without any reference to actual villages, settlements, rivers, hills, swamps or other demographic and topological characteristics of the land.'[61]

Semiotically, we cannot understand this modernist vision of agriculture as an isolated ideological fragment. It is always seen as the negation of the existing rural world. A kolkhoz is meant to replace a mir or village, machines to replace horse-drawn ploughs and hand labour, proletarian workers to replace peasants, scientific agriculture to replace folk tradition and superstition, education to replace ignorance and *malokulturnyi*, and abundance to replace bare subsistence. Collectivization was meant to spell the end of the peasantry and its way of life. The introduction of a socialist economy entailed a cultural revolution as well; the 'dark' narod, the peasants who were perhaps the great remaining, intractable threat to the Bolshevik state, were to be replaced by rational, industrious, de-Christianized, progressive-thinking kolkhoz workers.[62] The scale of collectivization was intended to efface the peasantry and its institutions, thereby narrowing the gulf between the rural and urban worlds. Underlying the whole plan, of course, was the assumption that the great collective farms would operate like factories in a centralized economy, in this case fulfilling state orders for grain and other agricultural products. As if to drive the point home, the state confiscated roughly 63 per cent of the entire harvest in 1931.

From a central planner's perspective, one great advantage of collectivization is that the state acquired control over how much of each crop was sown. Starting with the state's needs for grains, meat, dairy products and so on, the state could theoretically build those needs into its instructions to the collective sector. In practice, the sowing plans imposed from above were often wholly unreasonable. The land departments, which prepared the plans, knew little about the crops they were mandating, the inputs needed to grow them locally, or local soil conditions. Nevertheless, they had quotas to fill, and fill them they did. When, in 1935, A. Iakovlev, the head of the Central Committee's agricultural department, called for collective farms to be managed by 'permanent cadres' who 'genuinely knew their fields', he implied that the present incumbents did not.[63] We catch a glimpse of the disasters from the Great Purges of 1936–1937, when a certain amount of peasant criticism of kolkhoz officials was briefly encouraged in order to detect 'wreckers'. One kolkhoz was instructed to plough meadows and open land, without which they could not have fed their livestock. Another received sowing orders that doubled the previous acreage allotted for hay fields by taking in private plots and quicksands.[64]

The planners clearly favoured monoculture and a far-reaching, strict division of labour. Entire regions, and certainly individual *kolkhozy*, were increasingly specialized, producing only, say, wheat, livestock, cotton or potatoes.[65] In the case of livestock production, one kolkhoz would produce fodder for beef cattle or hogs while another would raise and breed them. The logic behind kolkhoz and regional specialization was roughly comparable to the logic behind functionally specific urban zones. Specialization reduced the number of variables that agronomists had to consider; it also increased the administrative routinization of work and hence the power and knowledge of central officials.

Procurement followed a comparable centralizing logic. Starting with the needs of the plan and a usually unreliable estimate of the harvest, a series of quotas for every oblast, *raion* and kolkhoz was mechanically derived. Each kolkhoz then claimed that its quota was impossible to fulfil and appealed to have it lowered. Actually meeting a quota, they knew from bitter experience, only raised the ante for the next round of procurements. In this respect collective farmers were in a more precarious situation than industrial workers, who still received their wages and ration cards whether or not the factory met its quota. For the *kolkhozniki*, however, meeting the quota might mean starvation. Indeed, the great famine of 1933–1934 can only be called a collectivization and procurement famine. Those who were tempted to make trouble risked running afoul of a more grisly quota: the one for kulaks and enemies of the state.

For much of the peasantry, the authoritarian labour regime of the kolkhoz seemed not only to jeopardize their subsistence but to revoke many of the freedoms they had won since their emancipation in 1861. They compared collectivization to the serfdom their grandparents remembered. As one early sovkhoz worker put it, 'The *sovkhozy* are always forcing the peasants to work; they make the peasants weed their fields. And they don't even give us bread or water. What will come of all this? It's like *barschina* [feudal labour dues] all over again.'[66] The peasants began to say that the acronym for the Ail-Union Communist Party – VKP – stood for *vtoroe krepostnoe pravo*, or 'second serfdom'.[67] The parallel was not a mere figure of speech; the resemblances to serfdom were remarkable.[68] The kolkhoz members were required to work on the state's land at least half-time for wages, in cash or kind, that were derisory. They depended largely on their own small private plots to grow the food they needed (other than grain), although they had little free time to cultivate their gardens.[69] The quantity to be delivered and price paid for kolkhoz produce was set by the state. The kolkhozniki owed annual corvée labour dues for roadwork and cartage. They were obliged to hand over quotas of milk, meat, eggs and so on from their private plots. The collective's officials, like feudal masters, were wont to use kolkhoz labour for their private sidelines and had, in practice if not in law, the arbitrary power to insult, beat or deport the peasants. As they were under serfdom, they were legally immobilized. An internal passport system was reintroduced to clear the cities of 'undesirable and unproductive residents' and to make sure that the peasantry did not flee. Laws were passed to deprive the peasantry of the firearms they used for hunting. Finally, the kolkhozniki living outside the village nucleus (khutor dwellers), often on their old farmsteads, were forcibly relocated, beginning in 1939. This last resettlement affected more than half a million peasants.

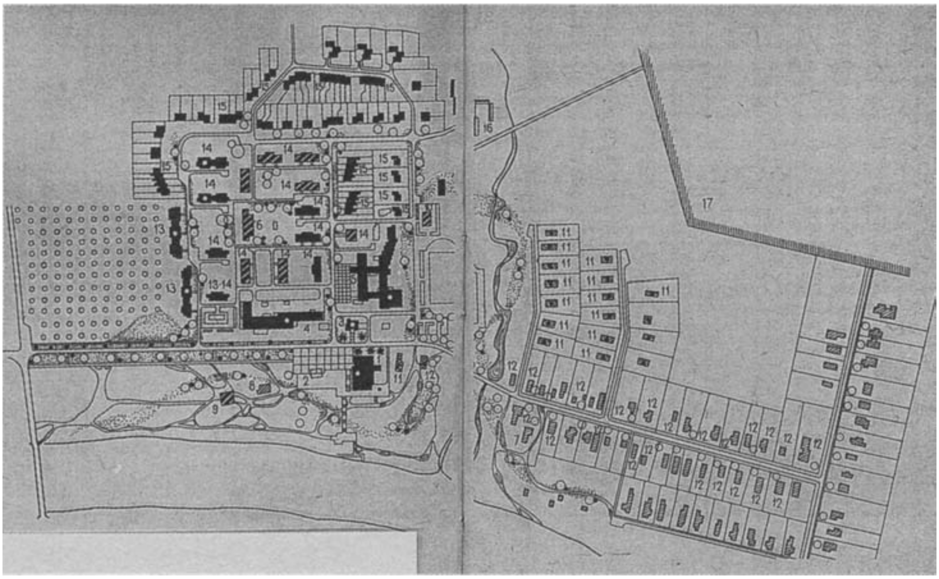
The resulting labour rules, property regime and settlement pattern did in fact resemble a cross between plantation or estate agriculture on one hand and feudal servitude on the other.

As a vast, state-imposed blueprint for revolutionary change, collectivization was at least as notable for what it destroyed as for what it built. The initial intent of collectivization was not just to crush the resistance of well-to-do peasants and grab their land; it was also to dismantle the social unit through which that resistance was expressed: the mir. The peasant commune had typically been the vehicle for organizing land seizures during the revolution, for orchestrating land use and grazing, for managing local affairs generally, and for opposing procurements.[70] The party had every reason to fear that if the collectives were based on the traditional village, they would simply reinforce the basic unit of peasant resistance. Hadn't the village Soviets quickly escaped the state's control? Huge collectives, then, had the decided advantage of bypassing village structures altogether. They could be run by a board consisting of cadres and specialists. If the giant kolkhoz was then divided into sections, one specialist could be named manager of each, '"*like the bailiffs in the old days*" [of serfdom] as [one] … report wryly noted'.[71] Eventually, except in frontier areas, practical considerations prevailed and a majority of the kolkhozy coincided roughly with the earlier peasant commune and its lands.

The kolkhoz was not, however, just window dressing hiding a traditional commune. Almost everything had changed. All the focal points for an autonomous public life had been eliminated. The tavern, rural fairs and markets, the church and the local mill disappeared; in their places stood the kolkhoz office, the public meeting room, and the school. Nonstate public spaces gave way to the state spaces of government agencies, albeit local ones.

The concentration, legibility and centralization of social organization and production can be seen in the map of the state farm at Verchnyua Troitsa (Upper Trinity) in Tver Oblast (Figure 14.1).[72] Much of the old village has been removed from the centre and relocated on the outskirts (legend reference 11).[73] Two-story apartment houses containing 16 flats each have been clustered near the centre (legend references 13, 14, 15; see also Figure 14.2), while the local administration and trade centre, school and community building, all public institutions run by the state, lie close to the centre of the new grid. Even allowing for the exaggerated formalism of the map, the state farm is a far cry from the sprawl and autonomous institutional order of the precollectivized village; a photograph showing the old-style housing and a lane illustrates the stark visual contrast (see Figure 14.3).

Compared to Haussmann's retrofitting of the physical geography of Paris to make it legible and to facilitate state domination, the Bolsheviks' retrofitting of rural Russia was far more thoroughgoing. In place of an opaque and often obstinate mir, it had fashioned a legible kolkhoz. In place of myriad small farms, it had created a single, local economic unit.[74] With the establishment of hierarchical state farms, a quasi-autonomous petite bourgeoisie was replaced with dependent employees. In place, therefore, of an agriculture in which planting, harvesting and marketing decisions were in the hands of individual households, the party-state



1, community centre; *2*, monument; *3*, hotel; *4*, local administration and trade centre; *5*, school; *6*, kindergarten; *7–8*, museums; *9*, shop; *10*, bathhouse; *11*, old wooden house moved from new construction area; *12*, old village; *13–15*, two- and three-storey houses; *16*, garage (private); and *17*, agricultural sites (farm, storage, water tower and so on)

Figure 14.1 *Plan of the state farm at Verchnyua Troitsa (Upper Trinity) in Tver Oblast*

had built a rural economy where all these decisions would be made centrally. In place of a peasantry that was technically independent, it had created a peasantry that was directly dependent on the state for combines and tractors, fertilizer and seeds. In place of a peasant economy whose harvests, income and profits were well-nigh indecipherable, it had created units that were ideal for simple and direct appropriation. In place of a variety of social units with their own unique histories and practices, it had created homologous units of accounting that could all be fitted into a national administrative grid. The logic was not unlike the management scheme at McDonald's: modular, similarly designed units producing similar products, according to a common formula and work routine. Units can easily be duplicated across the landscape, and the inspectors coming to assess their operations enter legible domains which they can evaluate with a single checklist.

Any comprehensive assessment of 60 years of collectivization would require both archival material only now becoming available and abler hands than my own. What must strike even a casual student of collectivization, however, is how it largely failed in *each* of its high-modernist aims, despite huge investments in machinery, infrastructure and agronomic research. Its successes, paradoxically, were in the domain of traditional statecraft. The state managed to get its hands on enough grain to push rapid industrialization, even while contending with staggering inefficiencies,

Figure 14.2 *At Verchnyua Troitsa, one of the new village's two-storey houses, each containing 16 flats*

stagnant yields and ecological devastation.[75] The state also managed, at great human cost, to eliminate the social basis of organized, public opposition from the rural population. On the other hand, the state's capacity for realizing its vision of large, productive, efficient, scientifically advanced farms growing high-quality products for market was virtually nil.

The collectives that the state had created manifested in some ways the facade of modern agriculture without its substance. The farms *were* highly mechanized (by world standards), and they *were* managed by officials with degrees in agronomy and engineering. Demonstration farms really did achieve large yields, although often at prohibitive costs.[76] But in the end none of this could disguise the many failures of Soviet agriculture. Only three sources of these failures are noted here, because they will concern us later.[77] First, having taken from the peasants both their (relative) independence and autonomy as well as their land and grain, the state created a class of essentially unfree labourers who responded with all the forms of foot-dragging and resistance practised by unfree labourers everywhere. Second, the unitary administrative structure and imperatives of central planning created a clumsy machine that was utterly unresponsive to local knowledge or to local conditions. Finally, the Leninist political structure of the Soviet Union gave agriculture officials little or no incentive to adapt to, or negotiate with, its rural subjects. The very capacity of the state to essentially re-enserf rural producers, dismantle their institutions and impose its will, in the crude sense of appropriation,

Figure 14.3 *Houses along a lane in the old village at Verchnyua Troitsa*

goes a long way toward explaining the state's failure to realize anything but a simulacrum of the high-modernist agriculture that Lenin so prized.

State Landscapes of Control and Appropriation

Drawing on the history of Soviet collectivization, I shall now venture a few more frankly speculative ideas about the institutional logic of authoritarian high modernism. Then I shall suggest a way of grasping why such massive social bulldozing may have worked tolerably well for some purposes but failed dismally for others.

The headlong drive to collectivization was animated by the short-term goal of seizing enough grain to push rapid industrialization.[78] Threats and violence had worked, up to a point, for the harvests of 1928 and 1929, but each annual turn of the screw elicited more evasion and resistance from the peasantry. The bitter fact was that the Soviet state faced an exceptionally diverse population of commune-based smallholders whose economic and social affairs were nearly unintelligible to the centre. These circumstances offered some strategic advantages to a peasantry waging a quiet guerrilla war (punctuated by open revolt) against state claims. The state, under the existing property regime, could only look forward to a bruising struggle for grain each year, with no assurance of success.

Stalin chose this moment to strike a decisive blow. He imposed a designed and legible rural landscape that would be far more amenable to appropriation, control and central transformation. The social and economic landscape he had in mind was of course the industrial model of advanced agriculture – large, mechanized farms run along factory lines and coordinated by state planning.

It was a case of the 'newest state' meeting the 'oldest class' and attempting to remake it into some reasonable facsimile of a proletariat. Compared to the peasantry, the proletariat was already relatively more legible as a class, and not just because of its central place in Marxist theory. The proletariat s work regimen was regulated by factory hours and by man-made techniques of production. In the case of new industrial projects like the great steel complex at Magnitogorsk, the planners could start virtually from zero, as with Brasília. The peasants, on the other hand, represented a welter of small, individual household enterprises. Their settlement pattern and social organization had a historical logic far deeper than that of the factory floor.

One purpose of collectivization was to destroy these economic and social units, which were hostile to state control, and to force the peasantry into an institutional straitjacket of the state's devising. The new institutional order of collective farms would now be compatible with the state's purposes of appropriation and directed development. Given the quasi-civil war conditions of the countryside, the solution was as much a product of military occupation and 'pacification' as of 'socialist transformation'.[79]

It is possible, I believe, to say something more generally about the 'elective affinity' between authoritarian high modernism and certain institutional arrangements.[80]

What follows is rather crude and provisional, but it will serve as a point of departure. High-modernist ideologies embody a doctrinal preference for certain social arrangements. *Authoritarian* high-modernist *states*, on the other hand, take the next step. They attempt, and often succeed, in imposing those preferences on their population. Most of the preferences can be deduced from the criteria of legibility, appropriation and centralization of control. To the degree that the institutional arrangements can be readily monitored and directed from the centre and can be easily taxed (in the broadest sense of taxation), then they are likely to be promoted. The implicit goals behind these comparisons are not unlike the goals of premodern statecraft.[81] Legibility, after all, is a prerequisite of appropriation as well as of authoritarian transformation. The difference, and it is a crucial one, lies in the wholly new scale of ambition and intervention entertained by high modernism.

The principles of standardization, central control and synoptic legibility to the centre could be applied to many other fields; those noted in the accompanying table are only suggestive. If we were to apply them to education, for example, the most illegible educational system would be completely informal, nonstandardized instruction determined entirely by local mutuality. The most legible educational system would resemble Hippolyte Taine's description of French education in the 19th century, when 'the Minister of Education could pride himself, just by looking at his watch, which page of Virgil all schoolboys of the Empire were annotating at that exact moment'.[82] A more exhaustive table would replace the dichotomies with more elaborate continua (open commons landholding, for example, is less legible and taxable than closed commons landholding, which in turn is less legible than private freeholding, which is less legible than state ownership). It is no coincidence that the more legible or appropriable form can more readily be converted into a source of rent – either as private property or as the monopoly rent of the state.

The Limits of Authoritarian High Modernism

When are high-modernist arrangements likely to work and when are they likely to fail? The abject performance of Soviet agriculture as an efficient producer of foodstuffs was, in retrospect, 'overdetermined' by many causes having little to do with high modernism per se: the radically mistaken biological theories of Trofim Lysenko, Stalin's obsessions, conscription during World War II and the weather. And it is apparent that centralized high-modernist solutions can be the most efficient, equitable and satisfactory for many tasks. Space exploration, the planning of transportation networks, flood control, airplane manufacturing and other endeavours may require huge organizations minutely coordinated by a few experts. The control of epidemics or of pollution requires a centre staffed by experts receiving and digesting standard information from hundreds of reporting units.

On the other hand, these methods seem singularly maladroit at such tasks as putting a really good meal on the table or performing surgery. This issue is addressed

Table 14.1 *Legibility of social groups, institutions and practices*

	Illegible	*Legible*
Settlements	• Temporary encampments of hunter-gatherers, nomads, slash-and-burn cultivators, pioneers and gypsies • Unplanned cities and neighbourhoods: Bruges in 1500, medina of Damascus, Faubourg Saint-Antoine, Paris, in 1800	• Permanent villages, estates and plantations of sedentary peoples • Planned grid cities and neighbourhoods: Brasília, Chicago
Economic units	• Small property, petite bourgeoisie • Small peasant farms • Artisanal production • Small shops • Informal economy, 'off the books'	• Large property • Large farms • Factories (proletariat) • Large commercial establishments • Formal economy, 'on the books'
Property regimes	• Open commons, communal property • Private property • Local records	• Collective farms • State property • National cadastral survey
Technical and resource organizations		
Water	• Local customary use, local irrigation societies	• Centralized dam, irrigation control
Transportation	• Decentralized webs and networks	• Centralized hubs
Energy	• Cow pats and brushwood gathered locally or local electric generating stations	• Large generating stations in urban centres
Identification	• Unregulated local naming customs • No state documentation of citizens	• Permanent patronyms • National system of identification cards, documents or passports

at length in Scott (1998, ch. 8),[83] but some valuably suggestive evidence can be gleaned from Soviet agriculture. If we think of particular crops, it is apparent that collective farms were successful at growing some crops, especially the major grains: wheat, rye, oats, barley and maize. They were notably inefficient at turning out other products, especially fruits, vegetables, small livestock, eggs, dairy products and flowers. Most of these crops were supplied from the minuscule private plots of the kolkhoz members, even at the height of collectivization.[84] The systematic differences between these two categories of crops helps to explain why their institutional setting might vary.

Let us take wheat as an example of what I will call a 'proletarian crop' and compare it with red raspberries, which I think of as the ultimate 'petit-bourgeois crop'. Wheat lends itself to extensive large-scale farming and mechanization. One might say that wheat is to collectivized agriculture what the Norway spruce is to centrally managed, scientific forestry. Once planted, it needs little care until harvest, when a combine can cut and thresh the grain in one operation and then blow it into trucks bound for granaries or into railroad cars. Relatively sturdy in the ground, wheat remains sturdy once harvested. It is relatively easy to store for extended periods with only small losses to spoilage. The red raspberry bush, on the other hand, requires a particular soil to be fruitful; it must be pruned annually; it requires more than one picking, and it is virtually impossible to pick by machine. Once packed, raspberries last only a few days under the best conditions. They will spoil within hours if packed too tightly or if stored at too high a temperature. At virtually every stage the raspberry crop needs delicate handling and speed, or all is lost.

Little wonder, then, that fruits and vegetables – petit-bourgeois crops – were typically not grown as kolkhoz crops but rather as side-lines produced by individual households. The collective sector in effect ceded such crops to those who had the personal interest, incentive and horticultural skills to grow them successfully. Such crops can, in principle, be grown by huge centralized enterprises as well, but they must be enterprises that are elaborately attentive to the care of the crops and to the care of the labour that tends them. Even where such crops are grown on large farms, the farms tend to be family enterprises of smaller size than wheat farms and are insistent on a stable, knowledgeable workforce. In these situations, the small family enterprise has, in the terms of neoclassical economics, a comparative advantage.

Another way in which wheat production is different from raspberry production is that the growing of wheat involves a modest number of routines that, because the grain is robust, allow some slack or play. The crop will take some abuse. Raspberry growers, because successful cultivation of their crop is complex and the fruit is delicate, must be adaptive, nimble and exceptionally attentive. Successful raspberry growing requires, in other words, a substantial stock of local knowledge and experience.

Notes

1 The best source for a discussion about Soviet high modernism is probably Richard Stites, *Revolutionary Dreams: Utopian Vision and Experimental Life in the Russian Revolution* (New York: Oxford University Press, 1989). Its generous bibliography appears to cover most of the available sources.

2 This inference, we know, is not a distortion of the doctrines of liberalism. J. S. Mill, whose credentials as a liberal son of the Enlightenment are not in doubt, considered backwardness a sufficient justification for placing authoritarian powers in the hands of a modernizer. See Ernest Gellner, 'The Struggle to Catch Up,' *Times Literary Supplement*, 9 December 1994, p. 14. For a more detailed argument along these lines, see also Jan P. Nederveen Pieterse and Bhikhu Parekh, eds., *The Decolonization of the Imagination: Culture, Knowledge, and Power* (London: Zed Press, 1995).

3 Stites, *Revolutionary Dreams*, p19. Engels expressed his disdain for Communist Utopian schemes like these by calling them 'barracks Communism'.

4 One could say that Catherine the Great, being Prussian born and an avid correspondent with several of the Encylopedists, including Voltaire, came by her mania for rational order honestly.

5 Sheila Fitzpatrick, *The Russian Revolution* (Oxford: Oxford University Press, 1982), p. 119. The term 'gigantomania' was, I believe, also in use in the Soviet Union. The ultimate failure of most of the USSR's great schemes is in itself an important story, the significance of which was captured epigrammatically by Robert Conquest, who observed that 'the end of the Cold War can be seen as the defeat of Magnitogorsk by Silicon Valley' ('Party in the Dock,' *Times Literary Supplement*, 6 November 1992, p. 7). For an industrial, cultural and social history of Magnitogorsk, see Stephen Kotkin, *Magnetic Mountain: Stalinism as a Civilization* (Berkeley: University of California Press, 1995).

6 An interesting parallel can be seen in the French countryside following the Revolution, when campaigns called for 'de-Christianization' and offered associated secular rituals.

7 Stites, *Revolutionary Dreams*, p. 119. See also Vera Sandomirsky Dunham, *In Stalin's Time: Middle-Class Values in Soviet Fiction* (Cambridge: Cambridge University Press, 1976), for how, under Stalin, this austerity was transformed into opulence.

8 Stites, 'Festivals of the People,' chap. 4 of *Revolutionary Dreams*, pp. 79–97.

9 Ibid., p. 95. Through Sergey Eisenstein's films, these public theatrical reenactments are the visual images that remain embedded in the consciousness of many of those who were not participants in the actual revolution.

10 Composers and filmmakers were also expected to be 'engineers of the soul'.

11 Quoted in Stites, *Revolutionary Dreams*, p. 243.

12 Lenin, almost certainly influenced by another of his favourite books, Campanella's *City of the Sun*, wanted public sculptures of revolutionaries, complete with inspiring inscriptions, to be erected throughout the city: a propaganda of monuments. See Anatoly Lunacharsky, 'Lenin and Art,' *International Literature* 5 (May 1935): 66–71.

13 Stites, *Revolutionary Dreams*, p. 242.

14 This entire section is based on chaps. 2, 4 and 6 of a remarkable forthcoming book by Deborah Fitzgerald, *Yeoman No More: The Industrialization of American Agriculture*, to which I am greatly indebted. The chapter and page numbers that follow refer to the draft manuscript.

15 Ibid., chap. 2, p. 21.

16 As many commentators have emphasized, this redesigning of work processes wrested the control of production from skilled artisans and labourers and placed it in the hands of management, whose ranks and prerogatives grew as the labour force was 'de-skilled'.

17 Around 1920, much of the market for agricultural machinery made by US manufacturers was not in the United States, where farm sizes were still relatively small, but outside the country, in such places as Canada, Argentina, Australia and Russia, where farms were considerably larger. Fitzgerald, *Yeoman No More*, chap. 2, p. 31.

18 For a fascinating and more complete account of the Campbell enterprise, see 'The Campbell Farm Corporation', chap. 5, ibid. It's worth adding here that the economic depression for agriculture in the United States began at the end of World War I, not in 1930. The time was thus ripe for bold experimentation, and cost of buying or leasing land was cheap.

19 Wheat and flax are, in the terminology developed later in this chapter, 'proletarian' crops as opposed to 'petit-bourgeois' crops.

20 Fitzgerald, *Yeoman No More*, chap. 4, pp. 15–17.

21 See above, nn. 14 and 18.

22 Another such farm, and one with direct links to New Deal experimentation in the 1930s, was the Fairway Farms Corporation. Founded in 1924 by M. L. Wilson and Henry C. Taylor, both of whom were trained in institutional economics at the University of Wisconsin, the corporation was designed to turn landless farmers into scientific, industrial farmers. The capital for the new enterprise came, through intermediaries, from John D. Rockefeller. 'Fair Way' Farms would become the model for many of the New Deal's more ambitious agricultural programmes as Wilson, Taylor and many of their progressive colleagues in Wisconsin moved to influential positions in Washington under Roosevelt. A more searching account of the connection is in Jess Gilbert and Ellen R. Baker, 'Wisconsin Economists and New Deal Agricultural Policy: The Legacy of Progressive Professors' (unpublished paper, 1995). The 1920s were a fertile time for agricultural experimentation, partly because the economic slump for agricultural commodities after World War I prompted policy initiatives designed to alleviate the crisis.

23 Fitzgerald, *Yeoman No More*, chap. 4, pp. 18–27. For an account of industrial farming in Kansas and its link to the ecological disaster known as the dust bowl, see Donald Worster, *Dust Bowl: The Southern Plains in the 1930s* (New York: Oxford University Press, 1979).

24 Fitzgerald, *Yeoman No More*, chap. 4, p. 33. The plan's outline can be found in Mordecai Ezekial and Sherman Johnson, 'Corporate Farming: The Way Out?' *New Republic*, 4 June 1930, pp. 66–68.

25 Michael Gold, 'Is the Small Farmer Dying?' *New Republic*, 7 October 1931, p. 211, cited in Fitzgerald, *Yeoman No More*, chap. 2, p. 35.

26 Ibid., chap. 6, p. 13. See also Deborah Fitzgerald, 'Blinded by Technology: American Agriculture in the Soviet Union, 1928–1932,' *Agricultural History* 70, no. 3 (Summer 1996): 459–86.

27 Enthusiastic visitors included the likes of John Dewey, Lincoln Steffens, Rexford Tugwell, Robert LaFollette, Morris Llewellyn Cooke (at the time the foremost exponent of scientific management in the United States), Thurman Arnold, and, of course, Thomas Campbell, who called the Soviet experiment 'the biggest farming story the world has ever heard'. Typical of the praise for Soviet plans for a progressive, modernized rural life was this appraisal by Belle LaFollette, the wife of Robert LaFollette: 'If the Soviets could have their way, all land would be cultivated by tractors, all the villages lighted by electricity, each community would have a central house serving for the purpose of school, library, assembly hall, and theatre. They would have every convenience and advantage which they plan for the industrial workers in the city' (quoted in Lewis S. Feuer, 'American Travelers to the Soviet Union, 1917–1932: The Formation of a Component of New Deal Ideology,' *American Quarterly* 14 [Spring 1962]: 129). See also David Caute, *The Fellow Travellers: Intellectual Friends of Communism*, rev. edn (New Haven: Yale University Press, 1988).

28 Feuer, 'American Travelers to the Soviet Union,' pp. 119–49, cited in Fitzgerald, *Yeoman No More*, chap. 6, p. 4.

29 Fitzgerald, *Yeoman No More*, chap. 6, p. 6.

30 Ibid., p. 37.

31 Ibid., p. 14.

32 Ibid., p. 39 (emphasis added).

33 Quoted in Robert Conquest, *The Harvest of Sorrow: Soviet Collectivization and the Terror-Famine* (New York: Oxford University Press, 1986), p. 232. An even more explicit recognition that this was a 'war' appears in this statement by M. M. Khateyevich: 'A ruthless struggle is going on

between the peasantry and our regime. It's a struggle to the death. This year was a test of our strength and their endurance. It took a famine to show them who was master here. It has cost millions of lives, but the collective farm system is here to stay, we've won the war' (quoted in ibid., p. 261).

34 The so-called Great Leap Forward in China was at least as deadly and may be analysed in comparable terms. I have chosen to concentrate on Soviet Russia largely because events there occurred some 30 years before the Great Leap Forward and hence have received much more scholarly attention, especially during the past seven years, when the newly opened Russian archives have greatly expanded our knowledge. For a recent popular account of the Chinese experience, see Jasper Becker, *Hungry Ghosts: China's Secret Famine* (London: John Murray, 1996).

35 In cases where yields were high among state farms and show projects, they were typically achieved with such costly inputs of machinery, fertilizers, pesticides and herbicides that the results were economically irrational.

36 For an exceptionally perceptive account of collectivization and its results, see Moshe Lewin, *The Making of the Soviet System: Essays in the Social History of Interwar Russia* (New York: Pantheon, 1985), especially part 2, pp. 89–188.

37 I use the term 'lumpen' here to designate a huge floating population of great variety and shifting occupations. Although Marx and Lenin always used the term scornfully, implying both criminal tendencies and political opportunism, I intend no such denigration.

38 Stalin, it is now believed, was personally responsible for drafting in August 1932 a secret decree branding all those who withheld grain, now declared to be 'sacred and untouchable' state property, as 'enemies of the people' and ruling that they should be summarily arrested and shot. The same Stalin, at the Second Congress of Outstanding Kolkhozniks in 1935, championed the retaining of adequate private plots: 'The majority of kolkhozniks want to plant an orchard, cultivate a vegetable garden or keep bees. The kolkhozniks want to live a decent life, and for that this 0.12 hectares is not enough. We need to allocate a quarter to half a hectare, and even as much as one hectare in some districts' (quoted in Sheila Fitzpatrick, *Stalin's Peasants: Resistance and Survival in the Russian Village After Collectivization* [New York: Oxford University Press, 1995], pp. 73, 122).

39 Ibid., p. 432.

40 Orlando Figes, 'Peasant Aspirations and Bolshevik State-Building in the Countryside, 1917–1925,' paper presented at the Program in Agrarian Studies, Yale University, New Haven, 14 April 1995, p. 24. Figes also links these views to socialist tracts that date from at least the 1890s and that pronounced the peasantry doomed by economic progress (p. 28).

41 R. W. Davies, *The Socialist Offensive: The Collectivisation of Soviet Agriculture, 1929–1930* (London: Macmillan, 1980), p. 51.

42 Conquest, *Harvest of Sorrow*, p. 43.

43 Also, the collapse of urban enterprises, which would normally have supplied consumer goods and farm implements to the rural areas, meant that there was less incentive for the peasantry to sell grain in order to make purchases in the market.

44 See Orlando Figes's remarkably perceptive and detailed book, *Peasant Russia, Civil War: The Volga Countryside in Revolution, 1917–1921* (Oxford: Clarendon Press, 1989). Even near revolutions create a similar vacuum. Following the 1905 revolution, it took the czarist government nearly two years to reassert its control over the countryside.

45 The relative unity of the village was itself enhanced by the revolutionary process. The richest landlords had left or been burned out, and the poorest, landless families had typically gotten some land. As a result, the villagers were more socioeconomically similar and therefore more likely to respond similarly to external demands. Since many of the independent farmers were pressured to return to the commune, they were now dependent on the entire village for their household's allotment of the communal lands. Thus it is not hard to understand why, in those instances where the kombedy was an instrument of Bolshevik policy, it faced determined opposition from the more

representative village soviet. 'One government official from Samara Province claimed, with conscious irony, that the conflicts between the kombedy and the Soviets represented the main form of "class struggle" in the rural areas during this period' (ibid., p. 197). In the larger villages, some support for Bolshevik agrarian plans could be found among educated youth, schoolteachers and veterans who had become Bolsheviks while serving with the Red Army during World War I or the civil war (and who might have imagined themselves occupying leading roles in the new collective farms). See Figes, 'Peasant Aspirations and Bolshevik State-Building'.

46 There was also a tendency to hide income from craft, artisanal and trading sidelines as well as 'garden' crops. During this same period, it should be added, insufficient resources – manpower, draft animals, manure and seed – meant that some of the arable either could not be planted or could only produce yields that were far lower than usual.

47 Yaney, *The Urge to Mobilize*, pp. 515–516. For Yaney, the continuity in aspirations from what he terms 'messianic social agronomists' under the czarist regime to the Bolshevik collectivizers was striking. In a few cases, they were the same people.

48 Figes, *Peasant Russia, Civil War*, p. 250.

49 Hunger and flight from the towns had reduced the number of urban industrial workers from 3.6 million in 1917 to no more than 1.5 million in 1920 (Fitzpatrick, *The Russian Revolution*, p. 85).

50 Figes, *Peasant Russia, Civil War*, p. 321.

51 Quoted in Fitzpatrick, *Stalin's Peasants*, p. 39.

52 In theory, at least, the most 'advanced' were the state farms – the proletarian, industrial, collective farms in which workers were paid wages and no private plots were allowed. These farms also received the bulk of state investment in machinery in the early years. For production statistics, see Davies, *The Socialist Offensive*, p. 6.

53 Ibid., pp. 82–113.

54 Fitzpatrick, *Stalin's Peasants*, p. 4.

55 Conquest, *Harvest of Sorrow*, p. 183.

56 Andrei Platonov, *Chevengur*, trans. Anthony Olcott (Ann Arbor: Ardis, 1978).

57 M. Hindus, *Red Breed* (London, 1931), quoted in Davies, *The Socialist Offensive*, p. 209.

58 Davies, *The Socialist Offensive*, p. 205.

59 The size of collective farms remained enormous, even by American standards, throughout the Soviet period. Fred Pryor calculates that in 1970 the average state farm comprised more than 100,000 acres, while the average collective farm comprised over 25,000 acres. The state farms were greatly favoured in access to inputs, machinery and other subsidies. See Frederick Pryor, *The Red and the Green: The Rise and Fall of Collectivized Agriculture in Marxist Regimes* (Princeton: Princeton University Press, 1992), table 7, p. 34.

60 Fitzgerald, *Stalin's Peasants*, p. 105.

61 Ibid., pp. 105–106. One imagines that the soils and existing cropping patterns were also ignored.

62 As the Bolsheviks explained, 'The kolkhozy are the only means by which the peasantry can escape from poverty and darkness' (Davies, *The Socialist Offensive*, p. 282). Perhaps the best visual images of the culturally transforming properties of electricity, machinery and collectivization are found in Sergey Eisenstein's film *The General Line*, a veritable technological romance set in rural Russia. The film masterfully conveys the Utopian aspirations of high modernism by contrasting the plodding dark narod with his horse and scythe with images of electric cream separators, tractors, mowing machines, engines, skyscrapers, engines and airplanes.

63 Fitzpatrick, *Stalin's Peasants*, p. 194.

64 Ibid., pp. 306–309.

65 For an account of how an even more extreme version of regional specialization was imposed on the Chinese countryside, in violation of local soil and climatological conditions, see Ralph Thaxton, *Salt of the Earth: The Political Origins of Peasant Protest and Communist Revolution in China* (Berkeley: University of California Press, 1997).

66 Figes, *Peasant Russia, Civil War*, p. 304. The analogy took concrete form in many of the early revolts against collectivization, during which the peasantry destroyed all the records of labour dues, crop deliveries, debts, and so on, just as they had under serfdom.

67 Conquest, *Harvest of Sorrow*, p. 152.

68 The resemblances to serfdom are spelled out in some detail in Fitzgerald, *Stalin's Peasants*, pp. 128–139. For a careful and informed discussion of serfdom and comparisons to slavery, see Peter Kolchin, *Unfree Labor: American Slavery and Russian Serfdom* (Cambridge: Harvard University Press, 1987).

69 For an astute account by a Soviet journalist and human rights campaigner in the 1980s, indicating that the basic pattern had not greatly changed, see Lev Timofeev, *Soviet Peasants, or The Peasants' Art of Starving*, trans. Jean Alexander and Alexander Zaslavsky, ed. Armando Pitassio and Alexander Zaslavsky (New York: Telos Press, 1985).

70 I am persuaded by the historical accounts that characterize the mir as the peasantry's adaptation to a gentry and state that treated it as a collective unit for the purposes of taxation, conscription and some forms of servile dues. The periodic redivision of land among the households ensured that all had the means of paying their share of the head taxes, which were levied on the commune collectively. That is, the relative solidarity of the Russian repartitional commune is itself a result of a distinct history of relations with overlords. This claim is perfectly compatible with the fact that such solidarity, once in place, can serve other purposes, including resistance.

71 Fitzgerald, *Stalin's Peasants*, p. 106 (emphasis added).

72 I am immensely grateful to my colleague Teodor Shanin and his research teams, who are conducting comparative work on more than 20 collective farms, for making available to me the maps and photographs for this chapter. Particular thanks to Galya Yastrebinskaya and Olga Subbotina for the photograph of the older village of Utkino, founded in 1912 and located 20 miles from the city of Vologda.

73 Notice that the old-style houses that were not moved (legend reference 12) are themselves laid out on roughly equal plots along the main road. I do not know whether there were administrative reasons behind these forms in the 18th century, when the village was founded, or whether the original pioneers themselves laid out the grid. How the older houses that have been relocated were originally disposed is also a mystery.

74 The same logic, of course, applied to industry, in which large units are favoured over small factories or artisanal production. As Jeffrey Sachs has observed: 'Central planners had no desire to coordinate the activities of hundreds or thousands of small firms in a sector if one large firm could do the job. A standard strategy, therefore, was to create one giant firm wherever possible' (*Poland's Jump into the Market Economy* [Cambridge: Cambridge University Press, 1993]). In the context of the Soviet economy, the largest industrial unit was the huge steel complex at Magnitogorsk. It is now a stunning example of an industrial and ecological ruin. See also Kotkin, *Magnetic Mountain*.

75 For a more extensive treatment of the ecological effects of Soviet agriculture, see Murray Feshbach, *Ecological Disaster: Cleaning Up the Hidden Legacy of the Soviet Regime* (New York: 1995), and Ze'ev Wolfson (Boris Komarov), *The Geography of Survival: Ecology in the Post-Soviet Era* (New York: M. E. Sharpe, 1994).

76 I worked for six weeks in 1990 on a cooperative (ex-collective) farm in East Germany, on the Mecklenburg Plain, not too far from Neubrandenburg. The local officials were exceptionally proud of their world-class yields per hectare in rye and potatoes with high starch content grown for industrial uses. It was clear, however, that as an economic matter, the market cost of the inputs (labour, machinery and fertilizer) needed to produce these yields made this enterprise an inefficient producer by any cost-accounting standard.

77 There is no doubt that a number of bureaucratic 'pathologies' amplified the disaster of Soviet collectivization. They include the tendency of administrators to concentrate on specified, quantifiable results (e.g., grain yields, tons of potatoes, tons of pig iron) rather than on quality and the fact

that long chains of specialization and command shielded many officials from the larger consequences of their behaviour. Also, the difficulty of making officials accountable to their clientele, as opposed to their superiors, meant that the pathology of group 'commandism', on one hand, or individual corruption and self-serving, on the other, were rampant. High-modernist schemes in revolutionary, authoritarian settings like that of the Soviet Union are thus likely to go off the rails more easily and remain off the rails far longer than in a parliamentary setting.

78 The rush towards collectivization was momentarily halted by Stalin's famous 'Dizzy with Success' speech of March 1930, which prompted many to leave the collectives; however, it was not long before the pace of collectivization resumed. In order to have enough capital for rapid industrialization, 4.8 million tons of grain were exported in 1930 and 5.2 million tons in 1931, helping to set the stage for the famine of the years immediately following. See Lewin, *The Making of the Soviet System*, p. 156.

79 Compare this with Bakunin's forecast of what state socialism would amount to: 'They will concentrate all of the powers of government in strong hands, because the very fact that the people are ignorant necessitates strong, solicitous care by the government. They will create a single state bank, concentrating in its hands all the commercial, industrial, agricultural and even scientific producers, and they will divide the masses of people into two armies – industrial and agricultural armies under the direct command of the State engineers who will constitute the new privileged scientific-political class' (quoted in W. D. Maximoff, *The Political Philosophy of Bakunin: Scientific Anarchism* [New York: Free Press, 1953], p. 289).

80 The term 'elective affinity' comes from Max Weber's analysis of the relation between capitalist norms and institutions on one hand and Protestantism on the other. His argument is not one of direct causation but of 'fit' and symbiosis.

81 See books 4 and 5 in vol. 2 of Gabriel Ardant, *Théorie sociologique de l'impôt* (Paris: CEVPEN, 1965).

82 Quoted in Michel Crozier, *The Bureaucratic Phenomenon* (Chicago: University of Chicago Press, 1964), p. 239. As Abram de Swaan has noted, 'The nineteenth-century school regime does reveal some unmistakable similarities with the factory regime of that time: standardization, formalization and the imposition of punctuality and discipline were paramount in both' (*In Care of the State*, p. 61).

Alternatives to Slash-and-Burn: Challenge and Approaches of an International Consortium

Pedro A. Sanchez, Cheryl A. Palm, Stephen A. Vosti, Thomas P. Tomich and Joyce Kasyoki

The Challenge

The world has lost about half of its forests to agriculture and other uses, and 78 per cent of what remains is heavily altered, bearing little resemblance to the original forests (Bryant et al, 1997). About 72 per cent of the original 1450 million ha of tropical forests have been converted to other uses (Myers, 1991; FAO, 1997). Deforestation rates for the humid tropics were estimated to be 6.9 million ha/yr at the end of the 1970s (Lanly, 1982) and doubled to 14.8 million ha/yr by 1991 (Myers, 1993). More recent studies indicate that deforestation rates decreased by about 10 per cent in the 1990s (Durst, 2000). These values are fraught with methodological problems. Achard et al (2002) asserted that previous methods overestimated tropical deforestation rates by as much as 25 per cent. Brazil, the country with the largest area of tropical forests, reports that deforestation rates in the Brazilian Amazon increased by as much as 40 per cent from 2001 to 2002 (INPE, 2003). Despite these limitations, it is obvious that tropical deforestation and subsequent ecosystem degradation continue at alarming rates. They remain a major worldwide concern because of the high levels of plant and animal biodiversity these forests contain, the large carbon (C) stocks stored in them, and the many other ecosystem services tropical forests provide (Myers, 1993; Laurance et al, 1997).

Small-scale farmers often are viewed as the primary agents of deforestation (Hauck, 1974), accounting for as much as 96 per cent of forest losses (Amelung and Diehl, 1992). Myers (1994) reported that the aggregate actions of small-scale farmers resulted in greater deforestation than the activities of large-scale operations

Reprinted from *Slash and Burn Agriculture* by Palm C A, Vosti S A, Sanches P A and Ericksen P (eds).

and accounted for about 70 per cent of the deforestation in Africa, 50 per cent in Asia, and 30 per cent in Latin America. Although the predominant role played by small-scale farmers has come into question (Geist and Lambin, 2002), they are often part of the deforestation process.

Small-scale farmers practising slash-and-burn agriculture clear forests to produce food and make a living for their families. They often have few options other than to continue clearing tropical forests because of the benefits and profits derived from deforestation. In many cases, these farmers are marginalized from society and government support programmes, and often they are migrants escaping from poverty and inequities elsewhere in the country. Any efforts to arrest deforestation must consider this group; in the absence of alternatives they will continue to clear forest to meet their needs for food and income.

Early approaches to conserve tropical forests were done at the exclusion of small-scale farmers that depend on the forest for their livelihoods (FAO Staff, 1957). These 'fence off the forest' approaches often increased conflicts between conservation and development efforts and ignored the causes of deforestation. The importance of agricultural development for reducing the poverty of the small-scale farmers and the economic development of developing countries is increasingly recognized. Therefore the development and promotion of agricultural systems that reduce poverty must be integrated with strategies to conserve tropical forests and the biodiversity and carbon they house (McNeely and Scherr, 2003). The challenges are to identify alternative systems that meet farmers' needs and that can reduce pressure to clear more forest or minimize the impacts on biodiversity and other global environmental resources. The Alternatives to Slash and Burn (ASB) consortium was created to address this challenge.

This chapter introduces the ASB Programme, an international consortium of researchers and extension groups that was established specifically to investigate the causes and consequences of deforestation by small-scale farmers and to identify land-use systems that enhance both local livelihoods and the environment and the policies and other changes needed to support them. It begins with a description and distinction of shifting cultivation and slash-and-burn practices and continues with a summary of land-use intensification pathways in the tropics. This is followed by the objectives, benchmark site locations, broad methods and activities of the ASB consortium.

Land Use at the Tropical Forest Margins

Almost all tropical forests are cleared by similar methods that start with slashing the forest with chainsaws, axes and machetes and burning the felled vegetation after it has dried. In this sense, slash-and-burn is simply a land-clearing technique. The subsequent land-use pathway that follows land clearing differs depending on the different groups of people involved – indigenous forest dwellers, small-scale farmers and large-scale private operators – and the intended use of the land, including the various types of shifting cultivation, agroforestry, logging, cattle ranching and commercial tree plantations. There is much confusion in the literature regarding the use of the terms *shifting cultivation* and *slash-and-burn agriculture*; the following sections distinguish between the different land-use pathways that follow the clearing of tropical forests.

Shifting cultivation or slash-and-burn agriculture?

Shifting cultivation is probably the oldest farming system (Nye and Greenland, 1960) and is remarkably similar throughout the humid tropics. Farmers slash and burn a hectare or so of primary or tall secondary forest, grow food crops in polyculture for 1–3 years, and abandon the land to secondary forest fallow regrowth for 20–40 years, then repeat the cycle. This traditional shifting cultivation with short cropping periods and long secondary forest fallow periods is now rare, practised primarily by indigenous communities disconnected from the national economy. It is socially and environmentally sustainable (Thrupp et al, 1997), albeit at low levels of agricultural productivity and human population densities of less than 30 people per square kilometre (Boserup, 1965). Shifting cultivation is known by a variety of terms, referring mostly to cleared fields: *swidden* (Old English), *rai* (Sweden), *milpa*, *conuco*, *roza* (Latin America), *shamba*, *chitemene* (Africa), *jhum* (India), *kaingin* (Philippines), *ladang* (Indonesia and Malaysia) and many others. Fallows are commonly called bush fallow and *jachere* in Africa; *barbecho*, *capoeira* and *purma* in Latin America; and *belukar* and other terms in Indonesia. The concept of fallows in the tropics differs from that used in the temperate zone, where the term *fallow* normally means leaving the soil bare (Sanchez, 1999). The vegetative fallow phase restores carbon and nutrient stocks in the biomass, improves soil physical properties and suppresses weeds (Nye and Greenland, 1960; Sanchez, 1976; Szott and Palm, 1986).

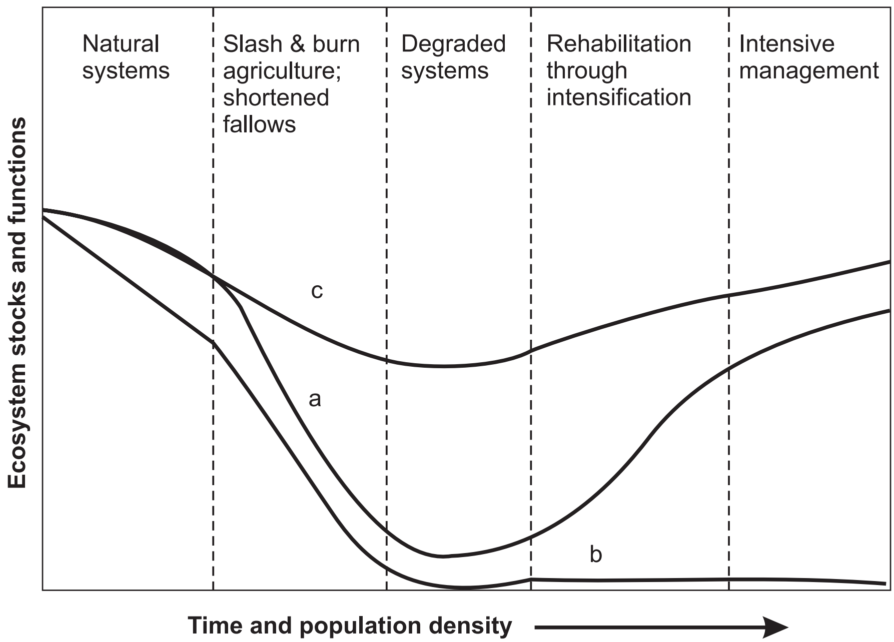
When human population pressures exceed a critical density that varies with agroecological zones and inherent soil fertility, traditional shifting cultivation is replaced by a variety of other agricultural practices that still involve clearing by slash-and-burn methods. We suggest that the loosely used terminology be specified as follows: *shifting cultivation* refers to the traditional long-fallow rotational system, and *slash-and-burn agriculture* refers to other farming systems characterized by slash-and-burn clearing, short-term fallows or no fallows at all. These systems include the shortened fallow–food crop systems and the establishment of tree-based systems such as complex agroforests, simple agroforests or monoculture tree crop plantations such as oil palm (*Elaeis guineensis* Jacquin), coffee (*Coffea* spp.), rubber (*Hevea brasiliensis* [Willd. ex A. Juss.] Muell.-Arg.) or pulp and timber species. Slash-and-burn is also the means of establishing pastures that are found throughout the humid forest zone of Latin America. These slash-and-burn systems differ from shifting agriculture in that the crops are interplanted with pastures or tree seedlings, or in some cases the cropping period is omitted. Many of the systems are still rotational to some degree, with occasional slash-and-burn clearing when the productivity of the system declines.

Land-use intensification pathways

The pathway of agricultural intensification depends to some extent on the biophysical environment but is modified by the demographic composition and pressures, production technologies, and natural resource management practices, infrastructure, institutions and policy environment present at the time. The usual pathway begins with the reduction of the fallow period to less than 10 years and more commonly less than 5 years. These short fallows are incapable of accumulating sufficient nutrient stocks in the biomass and suppressing weeds by shading. Unlike shifting cultivation, where soil erosion is seldom a problem, slash-and-burn systems have less vegetative cover and often exposed, compacted soils that increase water run-off and soil erosion rates (Lal et al, 1986). This change in vegetation and soil structure may lead to changes in the hydrologic cycle, with negative consequences downstream (Bruijnzeel, 1990; Tinker et al, 1996). The combined effects of shortened fallows result in systems with declining productivity, depending more and more on less and less fallow biomass. In some cases, the systems reach a point at which the trees are replaced by other, highly degraded systems such as *Imperata cylindrica* (L.) Beauv grasslands in South-East Asia and West Africa (Garrity, 1997) and degraded pastures in Latin America (Serrão and Homma, 1993). This pathway of land-use intensification, land degradation and the resulting losses of carbon stocks, nutrients and biodiversity is depicted in the left-hand, declining curve in Figure 15.1, line *a*. It is important to remember that those and other ecosystem services have been traded for private benefits, including food, feed, fibre and cash.

With further increases in population density come increased access to markets and decreased access to forest products. A point may be reached when land degradation begins to be reversed with changes in land tenure institutions that facilitate investments in improved land management. This process was recognized by Boserup (1965) and is sometimes called induced institutional innovation (Hayami and Ruttan, 1985). Land rehabilitation usually is accomplished by replenishing lost plant nutrients; using improved crop germplasm, agronomic practices and soil conservation methods; introducing livestock; and planting more trees.

Farmers will invest in improved land management and care for the environment when they have reasonably secure land or tree tenure and if it is profitable compared with other investment options within the context of household constraints and individual time preferences and attitudes toward risk. Examples of soil and land rehabilitation with increasing population pressure are well documented as ‘more people, less erosion’ (Tiffen et al, 1994) and ‘more people, more trees’ (Sanchez et al, 1998). They are accompanied by increasing productivity and profitability. Ecosystem stocks of carbon and nutrients increase and other ecosystems services also return, the level of which depends on the previous state of degradation and on the type of land-use system that is established. Livelihoods may continue to improve as more and more valuable economic products are obtained from the system. The trade-offs between the environmental services and profitability are



Note: Line *a* represents the usual pattern of land degradation and eventual rehabilitation when the proper policies and institutions are in place, line *b* represents the continued state of degradation that can occur in the absence of appropriate policies and institutions, and line *c* represents the desired course where there is little degradation of the resource base yet improved livelihoods are achieved.

Figure 15.1 *Land-use intensification pathways and changes in stocks of natural capital such as carbon and nutrient stocks, biodiversity and other ecosystem services, with time and increasing population density in the tropics*

lower than those in the degraded state. This is the right-hand side of Figure 15.1, line *a*. In some cases, the policy environment does not provide incentives to rehabilitate these degrading lands (line *b* in Figure 15.1), and the challenge is to find policy tools that will provide those incentives.

Alternative land-use intensification pathways that do not first involve severe land degradation (line *c* in Figure 15.1) do exist in the form of the complex agroforests that have been developed by indigenous communities (Padoch and de Jong, 1987; Michon and de Foresta, 1996; Duguma et al, 2001). The challenge is, first, to identify and understand barriers to adoption of other systems by smallholders when such systems are superior alternatives in terms of their environmental impacts and sustainability as well as their profitability, food security, riskiness and other measures of acceptability to smallholders. When such superior win–win alternatives exist, the next challenge is to identify means to reduce barriers to adoption by smallholders before land degradation occurs to such an extent that ecosystems services are lost. More often, however, there is no single 'best bet', but instead there is a range of trade-offs across land-use alternatives regarding environmental and agricultural development objectives.

Who are the small-scale slash-and-burn farmers?

The number of people who depend on shifting cultivation for their livelihoods has for decades been estimated at about 250–300 million (Hauck, 1974; Myers, 1994). Recent georeferenced population and farming system data suggest that the numbers are an order of magnitude lower. Dixon et al (2001) report that 37 million people, or 2 per cent of the agricultural population of the tropics, practise some form of shifting cultivation in about 1 billion ha or 22 per cent of the tropical land area. This is the area of influence, but only a small fraction of that is under actual cropping or fallows. These numbers do not include people practising more intense systems in the humid tropics that were originally established by slash-and-burn practices. The number of people involved in these other crop-based, tree-based or pasture-based slash-and-burn systems is several times that of shifting cultivators (Dixon et al, 2001).

Deforestation by slash-and-burn farmers is a response to underlying root causes. Population growth is naturally viewed as a main driver of deforestation, and economic growth often is viewed in the same vein. But no direct relationship between deforestation and population growth or economic growth has been found. Myers (1991) noted that whereas the population of forested tropical countries increased by 15–35 per cent in the 1980s, deforestation expanded by 90 per cent during the same period. The recent analysis by Geist and Lambin (2002) shows that in-migration to the forest margins is a much larger factor in deforestation than high internal population growth. Brown and Pearce (1994) obtained inconclusive results when attempting to relate gross domestic product (GDP) growth rates, foreign debt and population growth with deforestation in tropical countries. Rudel and Roper (1997) found that in tropical countries with large forested areas, deforestation increases with increasing GDP, whereas in countries with mainly forest fragments, increasing GDP decreases deforestation.

Whereas traditional, indigenous people practise shifting cultivation, many (in some cases most) of the people practising slash-and-burn agriculture are migrants from other parts of their country who seek a better life at the forest margins. In some countries, large numbers of migrants to the forest margins come as part of government-sponsored colonization programmes aimed at transmigrating poor people from densely populated areas to the forest frontier, particularly in Brazil and Indonesia (Hecht and Cockburn, 1989; Kartasubrata, 1991). Others are spontaneous migrants who, acting independently with little or no government support, follow the opening of roads and logging trails. Planned and spontaneous migrations of poor people from crowded regions such as Java, the Andes and north-eastern and southern Brazil have undeniably contributed to deforestation. Opening of roads into primary forests such as the Belém-Brasília, Transamazônica and São Paulo–Rio Branco in Brazil, the Carretera Marginal de la Selva and the Federico Basadre in Peru, and the Trans-Sumatra and Trans-Gabon highways have provided access to forests to both small-scale farmers and commercial interests.

Many of these migrants are unfamiliar with the humid tropics, are largely unaware of the knowledge-intensive practices of indigenous shifting cultivators, and attempt to establish cropping systems that work where they came from (Moran, 1981). People in these situations usually lack alternative employment opportunities; have limited access to markets, credit and information; and often are politically marginalized. These people are a major focus of the ASB consortium.

The ASB Consortium

The ASB consortium is an international group of researchers, extension workers and non-government organizations (NGOs) established in February 1992 to investigate the causes and consequences of deforestation by small-scale farmers and to identify land-use systems that enhance local livelihoods and the environment and the policies and other changes needed to support them. The ASB focuses on areas with high rates of deforestation where rapid increases in population density caused primarily by inmigration result in conversion of natural forests and where the environment–livelihood trade-offs are large. The ASB does not focus on shifting cultivation, but in some locations where it did occur, it was included in the comparative analysis. Similarly, larger-scale slash-and-burn operations also were included in some of the comparisons.

State of knowledge

A literature review undertaken in 1992 showed much process-based understanding of agricultural practices, empirical understanding of global environmental processes and social processes, some policy research, and almost no multidisciplinary research (Sanchez and Bandy, 1992; Bandy et al, 1993; Sanchez and Hailu, 1996). The biophysical processes of shifting cultivation and slash-and-burn systems have been well understood through decades of long-term, place-based research (Nye and Greenland, 1960; Jurion and Henry, 1969; Sanchez, 1976; Juo and Lal, 1977; Seubert et al, 1977; Serrão et al, 1979; Macintosh et al, 1981; Toky and Ramakrishnan, 1981; Sanchez et al, 1983, 1987; Ramakrishnan, 1984, 1987; Smyth and Bastos, 1984; Von Uexkull, 1984; Alegre and Cassel, 1986, 1996; Sanchez and Benites, 1987; Wade et al, 1988; Kang et al, 1990; Cerri et al, 1991; Palm and Sanchez, 1991; Smyth and Cassel, 1995; Juo and Manu, 1996; Palm et al, 1996).

The environmental consequences of slash-and-burn and tropical deforestation on greenhouse gas emissions have been modelled or estimated with limited data on the rates of deforestation, the carbon stored in the forests and subsequent land-use systems (Houghton et al, 2000). Much data have been gathered on the effects of tropical deforestation on above-ground biodiversity (Whitmore and Sayer, 1992; Heywood, 1995) and watershed hydrology (Bruijnzeel, 1990; Tinker et al, 1996), but with limited specificity to slash-and-burn agriculture. There were only a few studies on below-ground biodiversity (Lavelle and Pashanasi, 1989).

The anthropological aspects of shifting cultivation have been described extensively (Conklin, 1954, 1963; Cowgill, 1962; Padoch and de Jong, 1987; Thrupp et al, 1997), with more recent studies focusing on migrants practising slash-and-burn agriculture (Moran, 1981; Colfer et al, 1988; Rhoades and Bidegaray, 1987; Fujisaka et al, 1991). There have been several studies about the economics and policies of deforestation and slash-and-burn practices, focused primarily on Brazil (Mahar, 1988; Binswanger, 1991; Brown and Pearce, 1994; Mahar and Schneider, 1994).

What this incomplete literature review showed was an almost total absence of multidisciplinary work. Social and biophysical scientists have seldom worked together on slash-and-burn issues. There was no tradition of joint research and collaboration between economic groups and the environmental community dealing with this issue (Repetto and Gillis, 1988), or between the agricultural, economic and environmental communities. The ASB consortium was established to link the diverse research disciplines and the development community to address jointly the problems of deforestation, unsustainable land use and rural poverty at the humid forest margins.

Inception

A United Nations Development Programme (UNDP)-sponsored workshop was held in Porto Velho, Rondônia, Brazil, 16–21 February 1992, attended by 26 environmental policy makers and research leaders from eight tropical countries, five NGOs, six international agricultural research centres, three regional research organizations and six donor agencies (ASB, 1992). Participants concluded that a global effort was needed because the problem and impacts were global and that cross-site comparisons of causes and solutions could provide insights not possible from isolated studies. The participants created the ASB consortium, set the broad basis for collaboration, selected three initial benchmark sites, and formed a governing body to guide the intricate linkages and processes.

Two key recommendations of the Rio Earth Summit that was held later in 1992 provided international legitimacy to the ASB consortium. They appear in chapter 11, 'Combating Deforestation', of Agenda 21, as follows (Keating, 1993):

> Limit and aim to halt destructive shifting cultivation by addressing the underlying social and ecological causes.
>
> Reduce damage to forests by promoting sustainable management of areas adjacent to the forests.

Goal, hypothesis and objectives

The overall goals of the ASB consortium are to help reduce the rate of deforestation caused by slash-and-burn agriculture, rehabilitate degraded lands created by slash-and-burn, and improve the well-being of slash-and-burn farmers by providing economically and ecologically viable alternative land-use practices.

The underlying hypothesis at the inception of ASB was that intensification of agricultural systems on already cleared lands and rehabilitation of degraded lands at the humid forest margins would reduce deforestation. Although this hypothesis has since been shown to be too simplistic because the underlying behavioural assumptions were wrong (Angelsen and Kaimowitz, 2001), it provided a framework around which the programme focused its initial research objectives and activities:

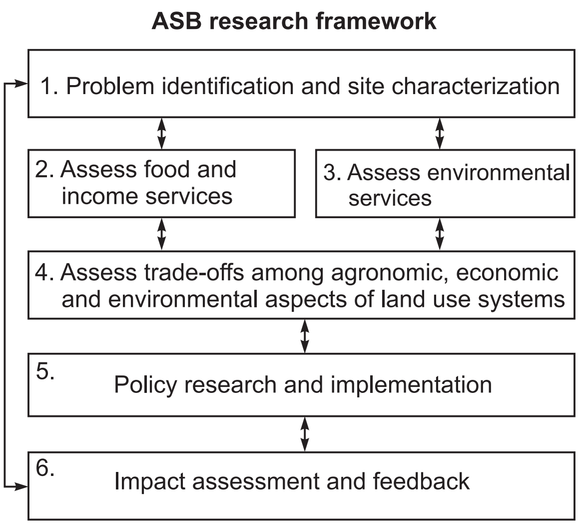
- *Site characterization*. Assess the principal socioeconomic and biophysical processes leading to deforestation, including government policy and decision-making patterns of farmers practising slash-and-burn.
- *Environmental and agronomic sustainability studies*. Quantify the contribution of slash-and-burn agriculture and alternative land-use practices to global, regional and local environmental changes such as climate change, biodiversity loss and land degradation.
- *Socioeconomic studies and trade-off analysis*. Integrated assessment of land-use alternatives to identify appropriate technologies and develop improved production systems that are economically feasible, socially acceptable and environmentally sound alternatives to current slash-and-burn systems or to understand trade-offs between land-use alternatives.
- *Policy research and implementation*. Identify policy options and institutional reforms that can facilitate the adoption of the improved systems and the balancing of trade-offs to attain a more desirable mix of outcomes and discourage further deforestation.

Succinctly stated, are there alternative land-use systems to slash-and-burn that reduce deforestation, poverty and global environmental changes such as greenhouse gas emissions and biodiversity loss? What are the type and magnitude of the environmental and livelihood trade-offs for these different systems? And, based on that trade-off analysis, how can the systems be influenced to attain better outcomes for a range of stakeholders, including farmers?

The slash-and-burn topic is complex, involving multiple agents, land-use objectives and driving forces (Tomich et al, 1998b). In addition, slash-and-burn is carried out in a diverse array of biophysical, socioeconomic and policy environments. To address the objectives of the ASB consortium requires an understanding of the influence of these multiple factors and environments on the economic viability, sustainability and environmental impacts of the alternatives. From the outset ASB determined four key features to assist in this complex task: a cross-disciplinary approach combining biophysical and behavioural sciences, the participation of diverse kinds of institutions, work based at benchmark sites, and common methods to be used at all sites. The benchmark sites and standard protocols are introduced in this chapter.

Cross-disciplinary research and development framework

The ASB developed a conceptual framework in which the land-use system adopted by farmers depends on farm households' objectives; their natural, human, social, technical and financial resources; and the biophysical, social, economic and political constraints to the use of these resources. The effects of these land-use systems for alleviating poverty, conserving resources and reducing deforestation were then assessed along with the impacts of current and alternative policies (Palm et al, 1995; ASB, 1996). An integrated natural resource management (INRM) research framework that was later developed by the international agricultural research centres (Figure 15.2; CIFOR, 2000; Izac and Sanchez, 2001) was based largely on the ASB experience. The various steps in the research process of problem identification, assessment of food and income services, assessment of ecosystem services, trade-off analysis, policy research and implementation, and impact analysis are discussed in the following sections.



Source: Modified from ASB, 1996; CIFOR, 2000; Izac and Sanchez, 2001)

Figure 15.2 *The research and development framework used by ASB*

Diverse institutions

In 2001 the ASB consortium was composed of seven national agricultural research systems, four other national agencies, seven international agricultural research centres, 20 universities and advanced research institutions, and five local and national NGOs. The ASB researchers have organized themselves in an evolving collection of multidisciplinary thematic working groups, including site characterization, biodiversity (above- and below-ground), climate change, agronomic sustainability, sustainable land-use mosaics, farmer concerns, policy and institutional issues, synthesis and linkages, and training and capacity building. A Global Steering Group provides governance to the consortium. It meets yearly and sets overall policy, funding strategy and reporting. A global coordinator with a small global team of two to three staff facilitates operations (Swift and Bandy, 1995).

Benchmark sites

A network of benchmark sites was identified to represent large, active areas of deforestation caused by slash-and-burn practices. The sites that were selected provide a range of biophysical and socioeconomic conditions under which slash-and-burn occurs and include a land-use intensity gradient from traditional shifting cultivation to intensive continuous cropping and degraded lands. Benchmark sites were also selected based on sufficient infrastructure to conduct the research and development activities. Each benchmark site covers a large area and has a national research station as its physical base, but the bulk of the work is done locally with researchers, NGOs, extension services, farmers and policy makers.

Latin America

Two areas were selected in the Amazon Basin; they represent areas that have experienced rapid deforestation as a result of government colonization programmes (western Amazon Brazilian benchmark site) and other areas of lower population density and poor infrastructure where population densities are increasing through spontaneous migration from the overcrowded urban and Andean areas (Peruvian benchmark site). The site in the western Brazilian Amazon encompasses two colonization projects, Pedro Peixoto, Acre and Theobroma, Rondônia, and areas along the BR-362 highway. Settlements are all under government sponsorship, with migrants assigned 50- to 100-ha plots, and currently undergoing rapid development. The site headquarters is the Empresa Brasileira de Pesquisa Agropecuária (Embrapa)–Acre research centre, near Rio Branco. The Peruvian benchmark area focuses on Pucallpa and Yurimaguas in the Ucayali and Loreto regions of the Selva Baja. The site is managed from the Center for Forestry Research (CENFOR) of the Instituto Nacional de Investigación Agraria (INIA), working in close cooperation with Consorcio para el Desarrollo Sostenible de Ucayali (CODESU), a group of NGOs, the Ucayali Regional Government, the Instituto de Investigación de la Amazonía Peruana (IIAP), and INIA's Yurimaguas Experiment Station.

A third area in Latin America represents the humid and subhumid forests of the Atlantic Coast of Central America and Mexico where encroaching urban areas and slash-and-burn has reduced the extent of the northernmost extension of tropical forests. The benchmark area in the Yucatan in south-east Mexico was managed by Instituto Nacional de Investigación Forestales, Agricolas y Pecuarias (INIFAP).

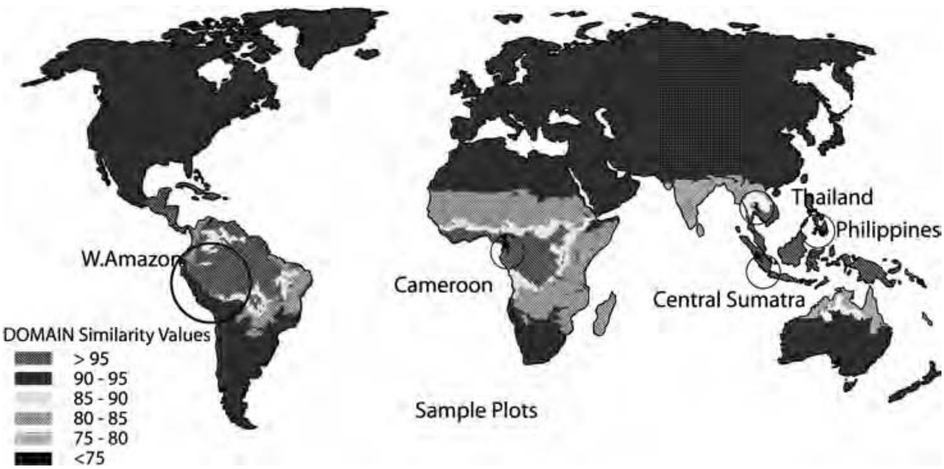
Africa

A site in Cameroon represents the equatorial Congo Basin rainforest of Congo–Kinshasa, Congo–Brazzaville, Equatorial Guinea, Gabon, Central African Republic, and Cameroon, where there is low but increasing population density and largely indigenous slash-and-burn agriculture. The site includes a north–south gradient, from rapid, spontaneous colonization around Yaoundé at the north, though an intermediate situation at M'Balmayo, to very low population density at Ebolowa in the southern end, close to the Gabon–Equatorial Guinea border. Site headquarters are at the Institut de Recherche Agricole pour le Développement (IRAD) at Nkolbisson, near Yaoundé, with strong support from the IITA Humid Forest Centre.

South-East Asia

Sites in South-East Asia represent three quite different forest ecosystems. The Sumatran benchmark area in Indonesia represents the equatorial rainforests of the Indonesian and Malaysian archipelago. Located in Jambi and Lampung provinces, it covers a broad gradient from primary forests in the Jambi area to degraded *Imperata* grasslands in Lampung Province, including both indigenous farmers and colonization projects as well as large-scale plantations and logging companies. The site is managed from the Central Research Institute for Food Crops (CRIFC) of the Agency for Agricultural Research and Development (AARD) in Bogor, Java. A benchmark area in the Philippines represents the monsoonal forests, where only forest remnants exist on steep mountain slopes and degraded grasslands dominate the landscape. The sites in Claveria and Lantapan in Northern Mindanao, Philippines, are operated by the Philippine Council for Agriculture, Forestry, and Natural Resources Research (PCARRD) together with a number of other organizations. A benchmark area in the Ma Chaem watershed near Chiang Mai, Thailand, represents the extensive area of subtropical hill forests of mainland mountain South-East Asia found in Thailand, Myanmar, Laos, Vietnam and southern China. The site was chosen to extend ASB research into higher-elevation areas with broad ranges of slope conditions where issues of land-use management often overlap with issues of watershed management. The benchmark site is managed by Thailand's Royal Forest Department in close collaboration with Chiang Mai University.

All benchmark sites fall within the tropical and subtropical moist broadleaf forest biome (WWF, 2001). To indicate how much the benchmark sites represent other areas in the tropics, regional similarity classes were developed from a set of key physical, environmental determinants of plant growth. The DOMAIN potential



Note: The DOMAIN similarity values are based on elevation, potential evapotranspiration, total annual precipitation, precipitation in the driest month, precipitation range, minimum average monthly temperature and maximum average monthly temperature.

Source: Gillison, 2000

Figure 15.3 *Map indicating the location and global environmental representativeness of the ASB sites in western Amazon, Indonesia, Thailand, Philippines and Cameroon*

mapping procedure developed by Carpenter et al (1993) was used to generate the map shown in Figure 15.3 of matching climate surface values for each of 108 sample locations in ASB's benchmark sites in Brazil, Indonesia and Cameroon. The various similarity classes indicate the degree to which the ASB sites can be extrapolated over a global surface using the same climate variables.

Initial ASB research was concentrated in the Brazil, Cameroon and Indonesian benchmark sites, and these three thus serve as the focus for this chapter, although much progress has also been made in Thailand and Peru.

Research Themes and Methods

The ASB integrates a range of geographic sites, spatial and temporal scales, disciplines, and partner institutions. To implement the various steps of the interdisciplinary INRM research framework at the various sites demanded a minimum, common research approach for making cross-site comparisons. Standardized methods were developed for identifying problems and characterizing sites (Figure 15.2, step 1), quantifying the environmental, agronomic and socioeconomic parameters of the different land-use alternatives (steps 2 and 3), assessing the economic and environmental trade-offs (step 4), and researching and implementing policies (step 5). The various methods are described in detail in this section.

Characterizing sites

The first phase of ASB research involved characterizing the benchmark sites. The purpose of the characterization was to describe the biophysical, socioeconomic and policy settings of the sites, define the extent and process of slash-and-burn agriculture in forming land-use patterns, investigate the driving forces for slash-and-burn, develop typologies of slash-and-burn land-use systems that exist across the ASB sites, establish a baseline of information for future impact assessments, and provide regional and global extrapolation domains for research results. The results were used to identify research priorities and develop research protocols for the subsequent steps.

Guidelines were developed for characterizing the rates of forest conversion; dominant land-use systems; and the biophysical, socioeconomic and policy environments in which they are found at the regional, benchmark, community and farm and household scales (Palm et al, 1995). Within each benchmark site there are numerous communities that represent a range of demographic conditions and land-use histories that result in different local land-use patterns. The characterization process also included detailed interviews to establish the problems, opportunities, constraints and resources at the community and farm or household scales, the responses to which were important for identifying factors that affect decision making and driving forces of land use and for establishing research agendas for finding sustainable alternatives to slash-and-burn. Remote sensing and geographic information system (GIS) techniques were used to assess rates of deforestation and land-use patterns at the sites.

Site characterization results for the first three benchmark sites are documented by Ávila (1994) for Brazil, Ambassa-Kiki and Tiki Manga (1997) for Cameroon, and Gintings et al (1995) and van Noordwijk et al (1995) for Indonesia. Information is also presented in benchmark site reports (Tomich et al, 1998a; Kotto-Same et al, 2000; Lewis et al, 2002). A comparison of some of the key biophysical and socioeconomic conditions shows the broad range encompassed by benchmark sites (Table 15.1). Comparable activities and approaches for Mexico and the Philippines are presented in Haggar et al (2001) and Mercado et al (2001), respectively.

Meta-land-use systems

A set of meta–land-use systems was identified from the site characterization process that aggregates the broad range of specific land-use systems found in the diverse benchmark sites (ASB, 1996). Such systems were initially identified as 'best-bet' and 'worst-bet' alternative systems for specific benchmark sites (Tomich et al, 1998b). Meta–land-use systems include forests, complex agroforests, simple agroforests, crop–fallow rotations, continuous food crops, and pastures and grasslands (Table 15.2). This array of land uses covers a gradient often used by biophysical scientists to describe varying levels of disturbance of forest for agriculture (Ruthenberg, 1980; NRC, 1993). General descriptions of these meta–land-use systems and some specific examples are given here.

Table 15.1 *Selected site characterization parameters for the ASB benchmark areas*

Characterization parameter	*Western Amazon, Brazil*	*Southern Cameroon*	*Sumatran Lowlands, Indonesia*	*Selva Baja of Peru*	*Ma Chaem, North Thailand*
Rainfall (mm/yr)	1700–2400	1400–1900	2500–3000	1500–2200	1200–1500
Latitude	7–12°S	2–4°N	0–6°S	6–12°S	20°N
Months dry season (<100mm)	June–September	July–August; October–February	June–August	June–August	November–April
Dominant original vegetation	Tropical moist forest; semideciduous forest	Tropical moist forest; semideciduous forest	Tropical moist forest	Tropical moist forest	Tropical semideciduous montane forest
Predominant soils (US Soil Taxonomy)	Paleudults, hapludox	Kandiudults	Hapludox, kandiudox, kandiudults, dystrudepts	Paleudults, paleaqualfs	Haplustults, dystrustepts
Population density (people/km^2)	3–5	4–200	2–175	1–9	20
Farm size (ha/household)	15–250[a]	5–30	2–10	2–50	2.4–16
Agricultural wage (US$/d)[b]	6.25	1.21	1.67	2.5	1.45, 1.75[c]

Notes: [a] Indicates small-scale farms as initially defined for Brazil.
[b] Wage rates are from 1996–1997.

Forests

Undisturbed or so-called primary forests are rare in and around the benchmark sites. Disturbed forests, with some degree of logging, are dominant, with the intensity of logging low in Cameroon, where a few trees are harvested per hectare, intermediate in Brazil and Peru, and high in Indonesia and Thailand. Extractive reserves, where non-timber forest products are harvested, are perhaps best known in the Amazon, where Brazil nuts or castanha (*Bertholletia excelsa* Humb. & Bonpl.) and rubber are harvested from naturally occurring trees, but at all sites some amount of nontimber forest products is harvested from forests of the different categories. The concept of sustainably managed community-based forests is being developed at the Brazil benchmark site by Embrapa. Community-protected secondary forests are found in the Thailand site and in Sumatra, Indonesia.

Complex agroforests

Complex agroforests contain a wide variety of economic plant species and usually have a rotation time greater than 20 years. The complex agroforests of Indonesia are indigenous systems established over generations by local peoples living at the margins of tropical rainforests in Sumatra, Borneo and other islands (Torquebiau, 1984; Foresta and Michon, 1994). Primary or old secondary forests are slashed and burned, food crops, citrus and robusta coffee (*Coffea canephora* Pierre ex Froehner) are planted along with several trees species, and natural regeneration of forest species is allowed. The trees eventually shade out the crops, occupy different strata, and produce high-value products such as fruits, resins, medicines and commercially valuable timber. The main economic tree species include damar (*Shorea javanica* Koord. & Valeton), durian (*Durio zibethinus* Murray), duku (*Lansium domesticum* Corr.) and rubber. In the case of rubber, production declines after 20 or 30 years, and the slash-and-burn cycle typically begins again; some of the other tree species, notably damar, can have much longer cycles. Alternatively, agroforests can be managed with gap replanting that eliminates the need for subsequent slash-and-burn cycles. In either case, such agroforests, composed of hundreds of small plots managed by individual families, occupy large contiguous areas in Sumatra and can be mistaken for forests to the untrained eye. Biophysical scientists have documented the high productivity and ecosystem services provided by these agroforests (Michon and de Foresta, 1996; Michon, 1997). Plant diversity in the mature complex agroforests is on the order of 300 species/ha, which approximates that of adjacent undisturbed forests (420 plant species/ha). The richness of bird species in mature agroforests is approximately 50 per cent that of the original rainforest, and almost all mammal species are present in the agroforest (Foresta and Michon, 1994). The villagers in Krui, Lampung Province, who make a living from these complex agroforests, have an obviously higher standard of living than those neighbours who grow only food crops (Bouamrane, 1996).

Complex agroforests based on cacao (*Theobroma cacao* [Linn.]) as the major cash crop have been developed in humid forest margins of West Africa over the past century (Duguma et al, 2001). Jungle tea (*Camellia sinensis* [L.] Kuntze) complex agroforests occur in North Thailand, where the naturally occurring tea trees are left when the forest is cleared and fruit trees are interplanted. Jungle rubber is a complex agroforest occupying 3 million ha where most of the rubber is produced in Indonesia. Indigenous Bora communities of the Peruvian Amazon establish complex agroforests by interplanting trees in upland rice and cassava crops (Padoch and de Jong, 1987). Economic trees include peach palm (*Bactris gasipaes* Kunth) for fruits and heart of palm, *Inga* spp. for fruits and firewood, arazá (*Eugenia stipitata* McVaugh) for fruit, and timber trees such as mahogany (*Swietenia macrophylla* King) and tornillo (*Cedrelinga cataeniformis* Ducke).

Simple agroforestry systems and intensive tree-crop systems

Simple agroforestry systems usually contain fewer than five economic plant species, whereas tree-crop plantations include only one. Both systems may include a leguminous crop cover. These systems are common in many parts of the humid tropics, particularly where infrastructure is well developed. Nevertheless, most of these start with slash-and-burn, in some cases followed by food crops interplanted with tree seedlings. Intensive tree-crop systems include the classic monoculture plantations such as oil palm and rubber, timber plantations such as pine (*Pinus* spp.), *Eucalyptus* spp., and cypress (*Cupressus* spp.), and fast-growing pulpwood plantations such as *Acacia mangium* and albizia (*Paraserianthes falcataria* [L.] I. Nielsen). These systems can be vast and run by corporations or run by individual smallholder farmers.

Simple agroforestry systems have less plant diversity than complex agroforests, higher levels of management are needed, and the regeneration of forest species is restricted. Included in this category are shade coffee, cacao and coconut plantations found throughout the humid tropics and the peach palm-based systems in Latin America. A slightly more diverse system based on peach palm, Brazil nut (*Bertholletia excelsa*), and cupuaçú (*Theobroma grandiflorum* [Willd. ex Spreng.] Schum) has been developed at the western Brazilian Amazon site.

Food crop–fallow rotations

Traditional shifting cultivation with long-term fallows was only found in the southern reaches of the Cameroon benchmark site and is absent in or disappearing from the other sites. Fallows of 10 years or less are more common at the other sites and include either natural secondary forest fallows or managed fallows (Sanchez, 1999). In the northern parts of the Cameroon benchmark site, shortening of the fallow period has resulted in the invasion and dominance of the bush *Chromolaena odorata* (L.) R. M. King and H. Robinson, a member of the Asteraceae family.

Improved or managed fallows, where trees are planted into the fallow, are now being tried in some of the benchmark sites. The planted trees often are nitrogen-fixing legumes that restore soil fertility more rapidly and include *Inga edulis* Mart. in Brazil and Peru or *Calliandra calothyrsus* Meissner in Cameroon. Deliberately planted fallows of *Tithonia diversifolia* (Hemsl.) Gray, another Asteraceae, are commonly found in the uplands of South-East Asia, practised by indigenous communities

(Cairns and Garrity, 1999). Improved fallows using leguminous cover crops kept in the field for less than 2 years occur in Peru and include kudzu (*Pueraria phaseoloides* [Roxb.] *Benth*) (Sanchez and Benites, 1987), *Mucuna* spp., and *Centrosema macrocarpum* Benth. (Palm et al, 2002a).

Continuous food crop production

Continuous cropping is found in valley bottoms as irrigated paddy rice (*Oryza sativa* L.) in Indonesia, Peru and Thailand, but because it is so well established and is rarely associated with slash-and-burn and deforestation it was not included in the analysis by ASB (except in Thailand). In Cameroon and Thailand, intensive horticulture with high rates of use of mineral fertilizers and pesticides forms an important option near the large urban centres of Yaoundé and Chiang Mai. Cassava is grown continuously in the Lampung area of the Indonesian benchmark site, particularly on transmigration settlement sites, and often eventually degrades through invasion by *Imperata cylindrica* into landscape patches or large grasslands.

Pastures and grassland systems

Pastures for beef production dominate the deforested landscape in the Brazilian and Peruvian benchmark sites. These include traditional, extensive pasture systems that degrade within a decade or so, as well as more intensive grazing systems with improved grass species (*Brachiaria humidicola* [Rendle] Schweick; *B. brizantha* [Hochst.] Stapf) often mixed with pasture legumes such as *Pueraria phaseoloides*, *Desmodium ovalifolium* Wall, *Arachis pintoi Krap. & Greg.*, and others (Serrão et al, 1979; Serrão and Toledo, 1990). The pasture species are tolerant to aluminum toxicity and are normally planted into a preceding crop of upland rice or maize (*Zea mays* L.). In parts of Brazil, these pastures are rejuvenated by burning, ploughing and fertilizing a maize crop to which pastures are replanted.

Extensive areas of *Imperata cylindrica* grasslands occur throughout South-East Asia and parts of West Africa. This species is known as alang-alang in Indonesia and cogon in the Philippines. These grasslands are dominant in the Lampung area of the Indonesian benchmark site (Garrity, 1997). This coarse, unpalatable grass invades areas where the fallow cycle has been shortened and is basically a degraded system. It is difficult to eradicate and is maintained by frequent fires. Fortunately *Imperata cylindrica* grasslands do not occur in Latin America, where less invasive *Imperata* species exist and pose no major problems.

These meta–land-use categories were used to set up land-use intensity transects or chronosequences at several locations in each benchmark site where environmental, agronomic and socioeconomic factors were evaluated by standard protocols. Whenever and wherever possible the different measurements were all taken from the same plot, farm or location in the landscape. Natural forest was considered the point of departure for all land uses, and grasslands, short-fallow cultivation systems and pastures were included as the other endpoint, representing degraded conditions. The specific environmental, agronomic and socioeconomic measurements are described in the sections that follow.

Quantifying environmental, agronomic and socioeconomic parameters

Climate change

Tropical deforestation and land-use change contribute as much as 25 per cent of the annual flux of carbon dioxide (CO_2) to the atmosphere (IPCC, 2001), yet there is still much debate on this issue because of uncertainties in biomass estimates, rates of deforestation and land-use change sequences. Changes in carbon stocks and the associated sources or sinks of atmospheric CO_2 and fluxes of nitrous oxide (N_2O) and methane (CH_4), the three most important greenhouse gases, were measured in the different land-use systems at the Brazil, Cameroon, Indonesia and Peru benchmark sites. Whereas most previous studies have focused on measurements in the forest and grassland or continuous cropping systems – in other words, the extremes – the dataset from ASB included measurements from many of the tree-based systems that often dominate the landscape in the humid tropics (Wood et al, 2000).

Carbon stocks in the above- and below-ground vegetation and in the top 20cm of the soil were estimated by a combination of allometric equations (for converting tree diameters into biomass) and destructive harvest. The concept of the average amount of carbon stored in each of the land-use systems during the time course of the rotations, or time-averaged carbon, was used for comparing land-use systems with different rotation times. The standardized methods for sampling are presented in Woomer et al (2000) and Woomer and Palm (1998). Results are presented in Woomer et al (2000) and Palm et al (2002b).

Estimating N_2O and CH_4 fluxes entails intensive, long-term sampling. This was not possible at most of the ASB sites. To obtain some estimates for annual fluxes and seasonal patterns for the different land-use systems, N_2O and CH_4 fluxes were measured monthly over the course of 2 years in the Indonesia and Peruvian benchmark sites using static chamber techniques. The sampling protocol and results are detailed in Ishizuka et al (2002) and Palm et al (2002a).

Biodiversity

Tropical forests contain two-thirds of the estimated 250,000 world's terrestrial plant species, 90 per cent of world's insects, and many bird species (Osborne, 2000), making tropical deforestation a primary cause of global biodiversity loss (Heywood, 1995; Stork, 1997). The extent of biodiversity loss associated with different land-use systems has seldom been considered, although many traditional land management strategies have supported biodiversity maintenance (McNeely et al, 1995; McNeely and Scherr, 2003). Diversity of the above-ground vegetation and below-ground biota were measured in the range of land-use systems at the benchmark sites to address these issues.

Above-ground plant diversity was measured as the number of plant species occurring in transects in each land-use type but also according to plant functional types (PFTs) (Gillison and Carpenter, 1997). Assessing plant diversity in the tropics is time-consuming and difficult, necessitating expertise in tropical plant identification and classification. The functional analysis uses a combination of adaptive morphologic or functional features (leaf size class, leaf inclination class, leaf form and type) and enables rapid characterization by people with minimal training. It includes measures of site physical features, vegetation structure, species composition, and PFTs (Gillison, 2001, 2002). Results from the benchmark sites are found in Gillison (2000).

Assessing diversity of below-ground biota is even more complex than above-ground vegetation, partly because many of the species have never been identified but also because sampling strategies that capture the spatial heterogeneity of the different types of biota have not been developed. The ASB below-ground biodiversity group designed a prototype sampling strategy and focused on assessing the biodiversity of certain functional groups of soil biota including macrofauna (earthworms, ants and termites), nematodes, arbuscular mycorrhizal fungi and rhizobial microsymbionts. Methods and results are presented in Swift and Bignell (2001).

Agronomic sustainability

The majority of soils in the humid tropics are acid and have low native fertility (Sanchez, 1976). Crops planted after slash-and-burn benefit from the nutrients in the ash, but rapid nutrient depletion takes place with successive nutrient removal in crop harvests, nutrient leaching, run-off and erosion promoted by high rainfall, and rapid decomposition of soil organic matter after burning. Soil physical properties also degrade with exposure caused by removal of the protective vegetation, and weeds invade fields, both of which contribute to declining crop yields (Sanchez et al, 1987; Juo and Manu, 1996). The long vegetative fallow characteristic of traditional shifting cultivation restores soil physical properties, accumulates carbon and nutrients in the fallow biomass, and eradicates weed populations. But as fallows shorten, their ability to perform these functions diminishes. The sustainability of the different land-use systems depends on the ability to maintain these vital ecosystem functions. A set of measurements that could indicate the sustainability of the systems was developed and includes soil structure and biological activity, nutrient balances and replacement costs, and weeds, pests and diseases. These criteria were assessed for the different land-use systems and then, based on expert judgement, translated into scales indicating the relative degree of difficulty farmers would face in solving the problem.

Household economic and social concerns

Regardless of the global environmental benefits or agronomic sustainability of a land-use system, farmers cannot be expected to adopt it unless it contributes more to meeting household objectives, does not entail excessive risks, and is compatible with the social and cultural norms of the community. The promotion of systems with greater environmental benefits must specifically consider the profitability, labour needs, food security and equity issues associated with them, as well as the institutions needed.

Methods to assess these objectives, their social and institutional needs, and the ability of farm households and communities to meet these needs were developed by the ASB consortium (Tomich et al, 1998a; Vosti et al, 2000) and used to assess the alternative land uses within and across sites. Key parameters included profitability (measured in terms of economic returns to land and labour), labour and capital needs for establishing and maintaining land-use systems, the potential contribution of given land-use systems to meet household food security needs, and market and nonmarket institutional needs of specific land-use systems. Detailed results of these studies for Brazil, Cameroon and Indonesia are found in Vosti et al (2001), Gockowski et al (2001) and Tomich et al (2001).

Analysing trade-offs: The ASB matrix

Land use at the humid forest margins is perceived by three general sets of beneficiaries. The global community is interested in saving tropical forests, increasing carbon sequestration, reducing greenhouse gas emissions and preserving plant and animal biodiversity. Small-scale farmers are interested in household food security, property rights, the profitability of their farms and the institutions that support their goals. National policy makers occupy intermediate positions and can be the key actors. In 1996, ASB researchers developed a framework known as the ASB matrix to help evaluate the local, national and global impacts of the alternative land-use systems and guide their decisions (Table 15.3; Tomich et al, 1998b).

The evaluation criteria include the environmental, agronomic and socioeconomic impacts, previously described, for each of the land-use options. The matrix puts together the food and income functions with ecological functions (production, human welfare and environmental impacts) of each system, indicating the potential trade-offs between the perspectives and interests of different stakeholders. This framework is intended for use in selecting from among the land-use alternatives. The challenge is for the multiple stakeholders to weigh trade-offs between their varied objectives. The notion of best-bet alternatives was introduced to indicate the systems that provide the combination of environmental services, poverty level and economic growth that is most acceptable to society in the production (private) and environmental (global) functions. Some advantages and limitations of the matrix are discussed in Vosti et al (2000) and Tomich et al (1998b).

The analysis of the resulting trade-off matrix must be done with full participation of the various stakeholders and is crucial for achieving a common understanding of the different viewpoints, vested interests and potential conflicts associated with the different choices. An example of the types of trade-offs is that between the carbon stored in different land-use systems and the private profitability realized from them. There is no win–win alternative system that combines maximum carbon stocks with maximum farmer profitability. There is a lose–lose or worst-bet alternative: food crops followed by short fallows. But there are two medium-carbon systems that have high levels of farmer profitability: cacao–fruit tree complex

Table 15.3 *ASB matrix comparing the environmental, agronomic, socioeconomic and policy aspects of the alternative land-use systems*

Meta–Land-use systems	*Global environmental concerns*		*Agronomic sustainability*	*Smallholders' socioeconomic concerns*		*Policy and institutional issues*
	Carbon sequestration (above-ground time-averaged; Mt/ha)	Biodiversity (above-ground plant species per plot)	Plot-level production sustainability (overall rating)	Potential profitability (returns to land, US$/ha)	Employment (average labour input; d/ha/yr)	Production incentives at private prices (returns to labour; US$/d)
Forests						
Complex agroforests						
Simple agroforests; intensive tree crops						
Crop–fallow rotations						
Continuous annual crops						
Grasslands, pastures						

Source: Modified from ASB (1996)

agroforests and small-scale oil palm plantations. These are the best-bet alternatives for minimizing the trade-offs between carbon sequestration and farmer profitability, and one can envision how policies or programmes could be established to promote these systems to replace the other systems with low carbon and low profits.

Researching and implementing policies

Once the diverse stakeholders have decided which land-use systems provide the desired combination of production, human welfare and environmental services, such as the example just described, it is necessary to search for policy instruments that can balance these trade-offs and that will lead to a broad-based adoption of those desired systems. Typically, there are few (if any) proven policy or institutional mechanisms to address these environment–development trade-offs. ASB has been involved with various partners in policy research at different levels.

Assessing impact and providing feedback

The last step in the ASB research and development framework is the assessment of the impacts of the options thus devised (Figure 15.2). Although implementation of the various land-use alternatives that have been identified as best bets is still in progress, in its first decade of existence the ASB consortium has had impacts on scientific methods and improved datasets, national research institutions, global forums concerned with poverty, the environment, and deforestation in the tropics, and policy makers. A summary follows.

Impact on science

Perhaps the greatest impact on science has been the research process and framework designed and implemented by ASB. The research framework established the basis for integrated natural resource management research of the CGIAR centres (CIFOR, 2000). The ASB matrix and trade-off analysis provides a way to tackle complex problems and reconcile the interests of different stakeholders. ASB has also shown how the disciplinary strengths in climate change, biodiversity, agronomy, policy reform and adoption can be used in a balanced and positive way, with combined, mutually accepted standard methods.

Other scientific contributions relate to improved methods of data collection and analysis and include improved equations for estimating carbon in young and regrowing trees, where the original equations overestimated carbon by as much as 100 per cent (Ketterings et al, 2001); refinement of the concept of time-averaged carbon for comparing carbon stored in land-use systems with different rotation times (van Noordwijk et al, 1998); validation of the use of plant functional attributes for above-ground biodiversity assessment; methods for assessing below-ground soil biodiversity by the use of functional groups (Swift and Bignell, 2001); and the identification of agronomic sustainability indicators, which is a major advance in the concept of soil quality.

The ASB has enriched the scientific literature substantially, particularly with articles written by national colleagues in international journals, with almost 450 publications by the end of 2003.

Impact on national institutions

The country chapters in part IV of Palm et al (2005) identify many of the effects of the ASB consortium on the collaborating national institutes including implementing the cross-disciplinary research approach, moving much of the work away from experiment stations to farmer fields and communities, and developing meaningful dialogues with policy makers. In addition, the 'south–south' exchange between scientists and policy makers visiting the ASB sites has spurred the imagination of many, resulting in the direct transfer of knowledge generated at one site to another. Such visits and workshops, along with the publication efforts, have 'internationalized' many national partners, but this is an area in which a great deal of potential for impact remains to be tapped.

Impact on policy makers

Substantive and long-term interactions have developed between ASB researchers and national policy makers, based on the solid scientific foundation ASB brings to the discussions.

At the national level, work with the Indonesian Ministry of Forestry resulted in a presidential decree that recognized the property rights of the people managing the complex agroforests on government lands in Sumatra (Fay et al, 1998). ASB has also worked with the Indonesian government to address the devastating forest fires associated with El Niño events. Suggestions include selective restrictions on burning during El Niño events, monitoring and penalizing large companies that misuse fire to clear land, recognizing long-standing land claims to help minimize conflicts over land allocation, reducing or eliminating policies that depress timber prices, and encouraging people who clear land to sell excess wood rather than burn it. At the regional level ASB scientists have promoted enabling policies to support community-based forest management plots with the government of the State of Acre in Brazil and to provide credits for on-farm reforestation with the Ucayali regional government in Peru.

Impacts on global organizations and forums

ASB is now a systemwide programme of the CGIAR and an NGO accredited by the Global Environment Facility. The ASB network of well-characterized benchmark sites in the world's tropical moist forests has attracted the attention of other groups concerned with the issues of poverty, the environment and deforestation at the forest margins. This includes the World Bank, the Asian Development Bank, the International Fund for Agricultural Development (IFAD), many bilateral donors, the Intergovernmental Panel on Climate Change (IPCC), the Millennium Ecosystem Assessment, the Rainforest Challenge Partnership and many others. Many of the approaches and results are being mainstreamed as new projects emerge. The methods for assessing carbon stocks and the improved estimates from the ASB assessment have been recognized and used by the IPCC (Paustian et al, 1997; IPCC, 2001).

External reviews

The ASB consortium has been periodically evaluated by external teams (Eswaran, 1995; Hansen et al, 1997; Technical Advisory Committee [TAC], 2000). The review by the Scientific and Technical Advisory Panel of the Global Environment Facility considered ASB 'exceptional and pioneering in its design, coverage, methodology, organization and scope for transferability and replicability' (Hansen et al, 1997, p1). According to TAC (2000, pxxi), 'the Alternatives to Slash and Burn Programme has gone further than others in relating its research sites to the whole area over which the problem occurs, and in scaling up to the global level in its findings on trade-offs. This is very helpful for the global debate on sustainability issues'. These positive reviews should be balanced with the real limitations of the ASB consortium, including recurring funding shortfalls and the communication challenge of keeping culturally diverse partners informed across the tropical belt.

The way forward

The first decade of the consortium was evaluated in 1999 at a conference in Chiang Mai on environmental services and land-use change. Details of the findings and recommendations are found in van Noordwijk et al (2001b) and Tomich et al (2004). Two of the major gaps that were identified included the assessment of hydrologic, ecological and other environmental services at the watershed or community scale and methods for the various stakeholders to develop workable responses and monitor the impacts of ongoing change.

A range of flexible tools will be identified and developed for communities, local government agencies, NGO activists, research managers, policy makers and other officials. Diverse stakeholders can then better explore their options to influence the individual choices that really determine the rate and pattern of land-use change (van Noordwijk et al, 2001b).

Conclusion

The ASB consortium has contributed scientifically and from a policy perspective to addressing the issues of poverty and deforestation in the humid tropics and has complied with the two Agenda 21 recommendations that formed the reason for its existence: 'Limit and aim to halt destructive shifting cultivation by addressing the underlying social and ecological causes' and 'Reduce damage to forests by promoting sustainable management of areas adjacent to the forests'. But tropical deforestation remains at alarming levels, and so do the poverty and harsh living conditions of most forest margins dwellers. The challenge has been partially met, and the response requires continuous hard work across the research–development continuum throughout the humid tropics. Latin American, African and Asian scientists have learned how to work together and have experienced first hand the benefits of cross-disciplinary and interinstitutional collaboration, working with international scientists, farming communities, government policy makers and leaders of international institutions, and are equipped with the methods and partners to meet this continuing challenge.

Modern Agricultural Reforms

16

Making Soil and Water Conservation Sustainable: From Coercion and Control to Partnerships and Participation

J. Pretty and P. Shah

Modernity and Soil Conservation

Dominant themes

Agriculture has had many 'revolutions' throughout history, from its advent some 10,000 years ago to the renowned 17th–19th-century agricultural revolution in Europe. In the past century, rural environments in most parts of the world have also undergone massive transformations. In some senses, these have been the most far-reaching in their speed of spread of new technologies and the nature of their impacts upon social, economic and ecological systems.

Two guiding themes have dominated these agricultural transformations. One has been the need for increased food production to meet the needs of growing populations. The other has been the desire to prevent the degradation of natural resources, perceived to be largely caused by growing numbers of people and their bad practices. Governments have encouraged the adoption of a wide range of conservation practices and technologies, including soil and water conservation to control soil erosion, grazing management schemes to control rangeland degradation, and exclusion of people from forests and other sites of high biodiversity to protect wildlife and plants.

These forms of agricultural and rural development appear to have been remarkably successful. Both food production and the amount of land conserved have increased dramatically, but both these results have been achieved within the framework of modernization, which is firmly rooted in, and driven by, the enlightenment tradition of positivist science (Habermas, 1987; Harvey, 1989; Rorty, 1989; Kurokawa, 1991). Scientists and planners identify the problem that needs solving,

---

Reprinted from Making soil and water conservation sustainable: From coercion and control to partnerships and participation by Pretty J and Shah P. 1997. *Land Degradation and Development* 8, pp39–58.

such as too much degradation. Rational solutions are proposed, and technologies known to work in a research station or other controlled environments are passed to rural people and farmers. The concern is thus to intervene so as to encourage rural people to change their practices.

Towards coercion with technologies

Central to this process of modernization is the assumption that technologies are universal, and so are independent of social context. New technologies are assumed to be better than those from the past, and so to represent 'progress'. Such a process is usually depicted as linear, with the new and modern displacing the old and 'traditional'. This iconography is powerful in many disciplines, and usually implies that what has gone before is not as good as what we have now.

The assumption of the universality of technologies has inevitably led to greater standardization. As farmers have been made to comply 'in their own best interests', they have done so only by completely changing their own livelihoods, and simplifying their practices to incorporate new technologies. External institutions have acted as if they alone know best.

Such universality of approach or technology leads to homogenization of environments. Where farmers used to grow tens of crop varieties, now they might only grow one or two. Where they used to use a range of biological and physical measures to control soil erosion, now they might only have terraces. Where they used to rely on wild plants and animals for food, medicine and fuel, now they might only rely on markets for these products. Modernization has brought with it the steady erosion of cultural and biological diversity.

This notion is not new. Modernity has sought to sweep away the confusion of diverse local practices and pluralistic functions accumulated over the ages, so as to establish a new order. This order is supposed to bring freedom from the constraints of history, and liberty in the new technologies and practices. This is captured in one of the slogans of the modernist architect, Le Corbusier, who said 'by order, bring about freedom'.

Throughout recent history, institutions concerned with encouraging soil and water conservation have had all the components of modernity. Farmers have been first encouraged, then later coerced, into adopting technologies that are known to work. When these farmers fail to maintain or others spontaneously to adopt these measures, then interventions have shifted to the remoulding of local social and economic environments to suit the technologies.

The contrast with what is required for more sustainable management of natural resources is crucial. Called by some postmodernism (coming after, or contrasting with, modernism), it favours heterogeneity, difference and human capacity as liberating forces. What postmodern traditions have in common is the rejection of 'meta-narratives', or large-scale plans, technologies or theoretical interpretations that purport to have universal application. The central theme is that all groups have a right to speak and act for themselves and their communities, in their own voices, and have their voice accepted as authentic and legitimate. If this is actively sought, then the positive effects on soil and water resources can be remarkable.

Modernization of Soil and Water Conservation in the US, Africa and South Asia

Beginnings in the US

The knowledge that soil erosion was both costly and damaging was first appreciated on a wide scale by agricultural authorities in the US in the 19th century, and in colonial Africa and India in the early part of the 20th century (Bennett, 1939; Hall, 1949; Pretty and Shah, 1994). Rural development policies and practice have generally taken the view that erosion occurs because farmers are poor managers of soil and water.

The style of intervention was first established in the US, where there is still a marked contrast between the enduring success of indigenous soil and water conservation and the approaches adopted by soil conservation authorities. Native American farming cultures farmed with soil and water conservation measures for at least 1500 years in the Greater South West. Farmers of Anasazi, Hohokam, Pueblo, Zuni, Hopi and Papago cultures located fields where water ran off hills, built earthen diversion dams and channels to conduct water, used contour bunds, stone terracing and contour hedges of agave, sited silt traps to produce gully fields, grew crops in mounds and on ridges, and stored run-off in reservoirs (Rohn, 1963; UNEP, 1983; Fish and Paul, 1992).

These combined to produce complex, diverse and productive agricultural systems. At Point of Pines, for example, 2500ha of cultivated land with contour terraces, check dams and bordered gardens supported at least 3000 people for 500 years, and in New Mexico, bordered gardens connected by ditches to vast rain catchment areas supported a population density of 700km^{-2}. Nonetheless, these systems were ignored by the modern conservationists.

At first confined to the southern States, soil conservation spread across most parts of the country in the early to mid-1800s. The principal technology was terracing, but this was supplemented by a wide range of other resource-conserving technologies, including contour ploughing, cross ploughing, green manures and cover crops, drainage ditches, check dams and hillside stripping with hedgerows (Hall, 1949). These technologies were developed, tested and adapted to local conditions by farmers. Until the late 1800s, technologies were derived from 'the experiences of practical planters and farmers'.

However, by the 1870s–1880s, things had begun to change. Terraces of various forms (broad base, bench, Nichols, Mangam, Chisholm and others) became increasingly popular. Although there were objections, e.g. that terraces took too much land out of cultivation and harboured weeds, increasing numbers of advisers, researchers and extensionists began to make wider recommendations based on terraces alone. Researchers at experimental stations, who at first had published bulletins and papers based entirely on the observations and experiences of 'progressive' farmers, later came to advocate technologies solely developed on research stations.

By the early 20th century, agricultural extension agencies and county agents 'built terraces for farmers and instructed them in terrace making and maintenance' (Hall, 1949). In the Alabama, Florida, Mississippi, North and South Carolina and Virginia regions, some 50,000ha were terraced in 1915; this had grown to 283,000ha by 1929. One pioneer county agent, J. F. Hart, laid out 98km of broad base terraces in 1914 alone.

By far the greatest boost to modern conservation ideology occurred when the Dust Bowl disaster struck the southern and southwestern states of Oklahoma, Arkansas, Kansas, Colorado, Texas and New Mexico during the 1930s. In the previous two decades, farmers had been encouraged to move westwards by favourable homestead policies and the high price of wheat (Worster, 1979). In the 1910s, 30,000 farmers each year registered new land holdings in these states, and in 1919 alone, some 4.5 million ha of grassland were ploughed up to grow wheat. By the time the dust storms began, much of the land had been farmed only for a generation. Eventually some 50 million hectares of farmland were said to be severely affected by erosion. Dust and earth blanketed houses and crops, and there were potent images of destruction, the landscape having become 'a vast desert, with … shifting dunes of sand' where there had once been crops (Worster, 1979).

These images of erosion linked farmers' cropping and grazing practices to increased frequency of droughts. The message was clear. Farmers caused land degradation which could lead to national ruin. At the time, several influential writers suggested that whole civilizations had collapsed through neglect of the soil (Bennett, 1939; Jacks and Whyte, 1939). The Head of the US Soil Conservation Service, Hugh H. Bennett, spoke of environmental catastrophe by indicating that 'the ultimate consequence of unchecked soil erosion, when it sweeps over whole countries as it is doing today, must be national extinction' (in Beinart, 1984). Over a relatively short period, policy makers came to treat the problem as so serious that widespread social and institutional action had to be taken.

As a result a federal Soil Conservation Service (formerly the Soil Erosion Service) was established in 1935 as a separate body to the existing extension service. Its agents conducted a national inventory of erosion, so that they could 'help the farmer do things correctly' (in Trimble, 1985). From the start, erosion was seen as a problem arising out of bad farming practices that had to be corrected. However, to demonstrate the efficacy of the approach, the SCS needed large amounts of land to practise the new large-scale engineering measures. As few agreements came from private farmers, they selected Navajo reservations on which to experiment (Kelly, 1985).

The SCS constructed physical measures and enforced compulsory destocking of sheep and goats. College graduates did the technical work, and local Navajos worked as labourers, but the project provoked an intense negative reaction, not only to soil conservation but also to all government programmes. Anthropologists discovered that the local people were not against soil conservation, but were opposed to the way it was being implemented (Kelly, 1985). They took exception to the locations of the measures, as these interfered with other activities. It was not a lack of interest that prevented them from maintaining or repairing the structures and earthen dams, but rather that the measures had been constructed with heavy equipment to which they had no access, and over which they had no control.

Conflict over budgeting and approach continued to hamper the SCS. Their approach was vigorously opposed by the extension service, whose agents at county level and in land-grant colleges had a good knowledge of the diversity of local conditions. The SCS applied terracing technology widely, whilst local agents argued for locally adapted and appropriate technologies, but the dissenting voices were ignored. Sauer was one of the few who indicated that construction without maintenance did more harm than good: 'the present erosion crisis is the result primarily of the introduction of terracing, originally thought of as protection against erosion' (Sauer, 1934, in Trimble, 1985).

Transfer to Africa

The pattern of intervention was repeated by colonial authorities in Africa. Erosion was first recognized as a problem as early as the 1870s, although it was not until the early part of the 20th century that concern grew over farming as practised by both indigenous people and colonial farmers. At first, farmers were encouraged to adopt soil conservation practices through publicity bulletins extolling the virtues of contour ploughing and grass strips, by establishing demonstration plots, and via local legislation (Stocking, 1985; Gichuki, 1991), but few farmers adopted the technologies, even though groups were taken to demonstration farms to see the benefits of the new farming practices.

New grazing management systems of enforced enclosure of grazing lands, developed in Texas, were also implemented. Again potent images of erosion spurred these efforts. In Kenya, Huxley (1960) described 'gullies 15–20 feet deep … in places, the landscape seems as dead as the moon's' in the west, and elsewhere the 'land is gashed … scraped bare, pounded into dust by the hoofs of little cattle and greedy goats'. It was clear to officials that local people were to blame. They sought technical guidance from the US, and brought back recommendations for large-scale conservation intervention. There were occasional dissenting voices. Writing in 1930, Sampson drew attention to indigenous methods of cultivation designed to check erosion, particularly mounding and ridge-and-furrowing systems on the contour. He indicated that local farmers 'fully realize the losses caused by erosion and consequent soil exhaustion, and their methods are well worth studying not only for themselves, but as a guide to those who seek to improve on them' (Sampson, 1930), but these sentiments were rare.

When these new soil conservation efforts proved to be too costly to sustain, particularly where mechanization was required, administrators increased the use of local labour rather than adapt the technologies (Anderson, 1984). They also put together the components of good conservation practice into farm plans. These were laid out on a blueprint chart showing what every field was to grow for 10 years, with all contours marked, the locations for woodlots, paddocks and homestead, and where to plant cash and food crops.

All of this required the monitoring of farming practices to ensure compliance. The final stage of control was achieved by the compulsory resettlement of farmers to centralized linear settlements where they could be observed more easily. In Kenya, more than one million people were moved in the mid-1950s to some 850 new linear villages (Huxley, 1960). Officials, proud of the new neatness and order, commented that farms of one village in Zimbabwe (then Rhodesia), were 'all in lines and look very nice' (Alvord, in Beinart, 1984).

This was a complete contrast to the traditional way villages in East and Southern Africa are arranged. Now many of the straight paths and tracks readily became gullies, as they concentrated water flow down slopes. The contrast again with traditional practices, where paths were laid out in zig-zag patterns, is significant (Wilson, 1989). Soil and water conservation had extended to the remoulding of all aspects of rural life.

Soil and water conservation in South Asia

As in the US and colonial Africa, there is a long history of both recognizing and ignoring local conservation practices in South Asia. The earliest accounts show that in 1888 some 1200ha of ravines in Uttar Pradesh were treated with conservation measures to protect the adjoining town of Etawah from water erosion. This was followed by tree planting, and fanners were coerced into adopting zero-grazing for livestock. The programme was acclaimed a success (PRAI, 1963).

At the same time, though, visitors were seeing local innovation and skills. Professor Voelcker, a consultant to the Royal Agricultural Society of England, visited India in 1889 and wrote in his report: 'Nowhere would one find better instances of keeping land scrupulously clean from weeds, of ingenuity in device of water raising appliances, of knowledge of soils and their capabilities as well as the exact time to sow and reap, as one would in Indian agriculture. It is wonderful, too, how much is known of rotation, the system of mixed crops and of fallowing. Certain it is that I, at least, have never seen a more perfect picture of careful cultivation, combined with hard labour, perseverance and fertility of resources' (in Dogra, 1983).

By 1928, the Royal Commission on Agriculture had recognized soil erosion as a problem of special importance, and had noted work already in progress: 'In the United Provinces, the main remedy for soil erosion has been sought in the afforestation of the ravine tracts. In Bombay [now Maharashtra State], the measures adopted to prevent soil erosion are terracing of land and the construction of earth and stone embankments.' The Famine Enquiry Commission of 1945 later indicated that the large-scale experiments conducted in Bombay had produced results sufficiently satisfactory to warrant contour bunding on a large scale. In Bombay, conservation work started in 1939 when the scheme for bunding and dry farming development was sanctioned. A similar act was passed in Madras in 1949 for contour trenching and bunding.

In the years that followed, conservation structures were constructed solely by the State. Although these were initially effective, it was soon realized that the approach could not be extended because of the high cost of operation and maintenance. The lack of involvement of farmers was also understood to be a problem, but at the same time they were considered to be ignorant. Most technical literature emanated from the US, and training opportunities for professionals were again on US Soil Conservation Service programmes.

The technocratic model of development of watersheds became the predominant approach at this stage and formed the basis for the formulation of 5-year plans and allocation of resources for soil conservation. These began with the objective 'to govern, regulate and administer the use of land both under private and public ownership, so as to facilitate the optimum use of land resources in the interests of the present and future generations' (Planning Commission, 1964), but the plans consisted of technical and engineering solutions with repeated emphasis on the education of farmers who had to be made aware of the new technologies. Problems with implementation and maintenance followed. When cultivators in Madhya Pradesh were reluctant to undertake earthwork, the department entrusted it to contractors. The contour bunding was completed with bulldozers, with no attention paid to the interests of farmers. In Maharashtra, Gujarat and Mysore, farmers were said to have taken to large-scale contour bunding, but it later became clear that 'the aspects of conservation farming practices or follow-up are neglected. As a consequence … the project is not serving the purpose for which it was set up' (Planning Commission, 1964).

Soil conservation continued with a technocratic emphasis. Between 1963 and 1990, national initiatives spent Rs4215 million (equal to US$149 million at current prices) on soil conservation in River Valley Projects (Fernandez, 1993), but farmers did not perceive any benefits from the structures. Indeed, many levelled and destroyed the measures because of the loss of cropland to conservation and the increase in observed soil erosion. The lack of compliance encouraged authorities to seek legal solutions. Several states passed laws to prevent 'wilful' destruction and to allow specified 'improvements' to be made on farmers' fields, and allocated the costs of these improvements between the farmers and the state. In some places, provisions were made for compulsory treatment of the fields of farmers refusing land treatment. In many cases this led to increased alienation with, for example, people uprooting plantations and destroying fencing and conservation measures.

Fundamental Contradictions of Recent Soil and Water Conservation Programmes

The 'complete' conservation technology package

Like other practices in agricultural development, most soil and water conservation programmes have begun with the notion that there are technologies that work, and it is just a matter of inducing or persuading farmers to adopt them. Yet few farmers are able to adopt whole packages of external technologies without considerable adjustments in their own practices and livelihood systems. To some, this may not be a problem; to the majority, it is a major impediment to adopting conservation technologies and practices.

A recent study of upland agriculture projects in six countries of South-East Asia found that farmers have not adopted resource-conserving technologies on a significant scale for a wide variety of social, economic and biological reasons (Fujisaka, 1991). Contour hedgerows, bench terraces, earth bunds, multiple cropping, legumes, perennial crops, contour tillage and alley cropping have all been introduced to farmers as they offer the opportunity for increased yields on a sustainable basis. In some cases, farmers' practices were ignored; in others the main problems for farmers, such as weeds, were not identified. Elsewhere, insecure land tenure prevented farmers investing in trees or terracing; in other places short-term incentives paid to farmers distorted local perceptions of conservation.

The problem is that the imposed models look good at first, and then fade away. Alley cropping, an agroforestry system comprising rows of nitrogen-fixing trees or bushes separated by rows of cereals, has long been the focus of research (Kang et al, 1984; Attah-Krah and Francis, 1987; Lal, 1989). Many productive and sustainable systems, needing few or no external inputs, have been developed. They stop erosion, produce food and wood, and can be cropped over long periods, but the problem is that very few, if any, farmers have adopted these alley cropping systems as designed. Despite millions of dollars of research expenditure over many years, systems have been produced which are suitable only for research stations (Carter, 1995).

There has been some success, however, where farmers have been able to take one or two components of alley cropping, and then adapt them to their own farms. In Kenya, for example, farmers planted rows of leguminous trees next to field boundaries, or single rows through their fields, and in Rwanda, alleys planted by extension workers soon became dispersed through fields (Kerkhof, 1990).

However, the prevailing view tends to be that farmers should adapt to the technology. Of the Agroforestry Outreach Project in Haiti, it was said that 'Farmer management of hedgerows does not conform to the extension program… Some farmers prune the hedgerows too early, others too late. Some hedges are not yet pruned by two years of age, when they have already reached heights of 4–5 metres. Other hedges are pruned too early, mainly because animals are let in or the tops are cut and carried to animals… Finally, it is very common for farmers to allow some of the trees in the hedgerow to grow to pole size' (Bannister and Nair, 1990). The language used clearly indicates that what farmers are doing is bad. Yet it could also be interpreted as good for sustainability: farmers were making their own adaptations according to their own needs.

Lack of maintenance by local people

Despite decades of effort, soil and water conservation programmes have had surprisingly little long-term success in preventing erosion. On paper, the quantitative achievements of some programmes can appear impressive. Throughout the world, terraces have been built, trees planted and farmers trained on a massive scale. In Africa, huge areas of land have been protected in the short term by conservation measures (Table 16.1).

However, these have not been long-term successes. In virtually all these sites, structures and practices have not persisted. Projects assume that maintenance will occur. Yet as farmers are treated at best as labourers for construction, they have few incentives to maintain structures or continue with practices that they neither own nor have had a say in designing. All too often, impressive new structures and practices slowly disappear, leaving little evidence of interventions and institutions.

This was recognized in the early days of the SCS in the US. A 1941 study of some 520 terraced fields on 5000ha in the south found that most terraces had been 'improperly constructed' and poorly maintained (Carnes and Weld, 1941). The terraces had been constructed by the SCS, yet 83 per cent were not being maintained by the farmers on whose fields the measures were situated.

Sometimes, successes are reversed almost immediately. In an evaluation of World Food Programme-supported conservation in Ethiopia, the extent of the terracing was quoted as being 'impressive', yet monitoring found 40 per cent of the terracing broken the year after construction (SIDA, 1984). The project had expected that local people would bear all the costs of maintenance. Another example comes

Table 16.1 *Extent of large-scale soil conservation programmes in Africa*

Burkina Faso	120,000ha of graded bunds constructed 1962–1965
Ethiopia	1–5 million km of stone and soil terraces and bunds constructed on 300,000ha, and 80,000ha closed off from local people during the late 1970s to 1987
Lesotho	All the uplands were said to be protected by buffer stripping by 1960
Malawi (then Nyasaland)	118,000km of bunds were constructed on 416,000ha between 1945 and 1960
Malawi	288,000ha terraced between 1968 and 1977
Rwanda/Burundi	750,000ha terraced and planted with trees to 1960
Swaziland	112,000km of grass strips laid out to 1950
Tanzania	125,000ha of Kondoa completely destocked of cattle to 1979 to encourage hillside regeneration
Zambia (then North Rhodesia)	Half the native land in eastern province was said to be protected by contour strips by 1950

Sources: Stocking, 1985; Marchal, 1986; Reij, 1988; IFAD, 1992 from the Yatenga region of Burkina Faso, where 120,000ha of earth bunds constructed at high cost with machine graders in the early 1960s have now all but disappeared (Marchal, 1978, 1986). In the Majjia and Badéguicheri valleys of Niger, most of the 6000ha of earth bunds constructed between 1964 and 1980 are in an advanced state of degradation (Reij, 1988). In Sukumuland, Tanzania, where contour banks, terraces and hedges were forced upon farmers in the 1950s, almost no evidence remained of these conservation works by the early 1980s, and now 'erosion is extremely severe' (Stocking, 1985).

Graded and contour bunds developed for large-scale farming in the US are still widely applied in programmes in India. Even under heavy subsidies, most small farmers reject them (Kerr and Sanghi, 1992). These bunds leave corners in some fields, and so there is a risk of losing the piece of land to a neighbour. The central water course for drainage benefits only some farmers, while damaging the land of others. Contour farming is inconvenient when farmers use multi-row implements, and so is only suitable where the holding is large and tractors are available. Contour bunding without facilities for dealing with surplus water commonly breach, again concentrating water flow that quickly forms gullies. Therefore, it is not uncommon for entire bunds to be levelled as soon as project staff shift to the next village (Sanghi, 1987; Fernandez, 1993).

In Cape Verde, the state takes responsibility for erosion control by paying farmers to work on their own land. The result is that traditional practices are ignored as farmers take the money without influencing the project. *Socalco* terraces, for example, are built from top to bottom of steep slopes, with the result that foundations are often left hanging in the air (Haagsma, 1990). As Haagsma put it 'this does not stimulate … good cooperation between farmers and MDRP [the project]. It is difficult to eradicate the attitude "MDRP knows best".'

A major project in Niger was described by the implementing agency in this way: 'People's participation is the power behind the Keita project. From decision-making – to planning – to action: local farmer-livestock owners have been consulted and actively taken part in every step' (FAO, 1992). Although some 2.76 million work-days were paid for with World Food Programme rations, which served as 'incentives to participate in land reclamation and training courses offered by the project', no farmers apply the technologies to their own lands, and replicability is close to zero (IFAD, 1992).

In Ethiopia, where 1.5 million km of terracing were constructed during the 1980s with food for work, participation was 'either compulsory via peasant association campaigns or paid through food for work' (SIDA, 1984). A total of 34.3 million person-days of work was devoted to conservation, involving the 'cooperation of some 8000 Peasant Associations' (FAO, 1986, in Östberg and Christiansson, 1993). Apparently, 'farmers' participation was shown by their contributions of labour for infrastructure development', and the project expected these structures to be maintained because 'training … will help in sustaining activities when the donor pulls out. The privilege of being trained will keep the individual responsible in the activities he (sic) was trained for' (reported in Oxfam, 1987).

Most soil and water conservation projects have paid and continue to pay local people in cash or food for their 'participation' (Kerr, 1994). But this is clearly self-defeating. According to Reij (1988): 'practice shows that where people are paid for soil and water conservation, the end of the project almost invariably leads to a stop in the construction of conservation works'.

More terracing yet more erosion

As a result of programmes not involving farmers in conservation, many have actually increased the amount of soil eroding from farms. Local people whose land is being rehabilitated have found themselves participating for no other reason than to receive food or cash. Seldom are the structures maintained, and so conservation works rapidly deteriorate, accelerating erosion instead of reducing it. If performance is measured over long periods, the results are extraordinarily poor for the amount of effort and money expended (Shaxson et al, 1989; Hudson, 1991; Reij, 1991; Shaxson, 1996).

Poorly designed structures cause erosion. Yet throughout Africa, little account has been taken of how more terracing can lead to more erosion. In the early 20th century, erosion in Lesotho was not a serious problem in cultivated fields, as grassed field boundaries were well developed and maintained (Showers, 1989). Yet the authorities ignored this indigenous practice, and installed contour banks. Local people did not approve, because these reduced the size of fields and were easily breached, causing gullies to develop leading to more erosion. The administration attributed these gullies to 'unusual weather' (Showers and Malahleha, 1990).

Elsewhere in southern Africa, the first anti-erosion measures introduced in the early 1930s were large ridge terraces and bunds, but these imported measures permitted storm water to break through at vulnerable points. Careless construction made them susceptible to bursting, and locals came to believe that 'gully erosion was caused by the government' (Beinart, 1984).

Narrow-based terraces were introduced into Kenya from the US in 1940 (Gichuki, 1991). For 15 years they were widely used. By 1947, some 4000ha were being protected each year, and this rate continued until 1956–1957. However, these terraces were found to fill up with sediments quickly, were impossible to maintain, and even began to aggravate erosion, and so by 1958 the number falling into disrepair was exceeding new construction. By 1961, some 20,000ha had fallen into disrepair. Eventually, the authorities recognized the problems and L. H. Brown, the chief agriculturalist, issued a memorandum in 1961 saying that 'narrow-based terraces should be abandoned as policy … we should move to strips of vegetation, preferably grass' (in Wenner, 1992).

Bad contour ridging in the 1960s was worse than none at all in Zimbabwe (then Rhodesia), where farmers say the compulsory construction of ridges caused siltation of rivers. The ridges connected whole fields and drained in a single drainage line. During severe storms, they concentrated water into powerful and fast-moving bodies that caused great damage (Wilson, 1989). The same thing has occurred with cut-off drains in Kenya. Their function was to intercept and divert storm water, but many were constructed in a way that caused erosion. As one review put it: 'The most severe mistakes were that cut-off drains were laid and constructed on the wrong sites. They were designed with steep gradients… The water is discharged into gullies which are deepening. The channel ridges were bare… All these factors have made the structures more dangerous than useful. More problems were created. Gullies have widened, soil was eroded and crops destroyed' (Hunegnaw, 1987).

More recently, in Malawi, the Lilongwe Land Development Programme (1968–1977) terraced some 288,000ha of land using heavy earth-moving machinery, but as farmers had few incentives to maintain these terraces, many of the diversion ditches silted up and breached to form severe gullies. The same story was repeated in nearby Swaziland from 1977–1983, where the Rural Area Development Programme built terraces with heavy machinery (IFAD, 1992). These destroyed all previous practices, but none of the new ones were maintained.

In Oaxaca, Mexico, a large-scale government soil conservation programme is also establishing contour bunds based on the US models. It is an area noted in the 1970s and 1980s by various 'expert' missions as having 'massive soil erosion' and 'the world's worst soil erosion', but recent evidence is suggesting that erosion has only become serious following the imposing of terraces and bunds (Blackler, 1994). Rill erosion has been recorded within one year of their establishment, and degradation has been so severe that less than 5 per cent of the bunded area is cropped.

Induced social disruption

The impact of these programmes has been to make many things worse. A failure to involve people in design and maintenance can have considerable long-term social impacts. The enforced terracing and destocking in Kenya, coupled with the use of soil conservation as a punishment for those supporting the campaign for independence, helped to focus the opposition against both authority and soil conservation (Gichuki, 1991; Pretty and Shah, 1994). After independence, this led to the deliberate destruction of many structures because of their association with the colonial administration (Anderson, 1984).

In Rwanda, the massive terracing programme using forced labour of the Belgian administration prior to 1960 created such negative feelings towards soil conservation that no further activities were possible until the late 1970s (Musema-Uwimana, 1983). In the Uluguru mountains of Tanzania, where ladder and step terraces were common, the Uluguru Land Usage Scheme introduced compulsory bench terracing in the 1950s – the scheme had to be abandoned after serious riots by local people (IFAD, 1992). Elsewhere in Tanzania, the HADO project completely removed livestock from whole communities, with tens of thousands of animals removed from individual districts. Such a policy was only possible 'after mustering the cooperation of the ruling party and government machinery at village, district, regional and national levels. Inevitably some of the actions necessary to reverse soil degradation processes are a bitter pill to swallow.' Despite this, the project staff believed that: 'the favourable results of destocking have sparked an interest in taking similar measures, particularly in the region's other districts' (in Mndeme, 1992).

In Somalia, a large FAO-funded project constructed dams during the 1970s to check gullies, but because of poor construction, many collapsed or diverted the floods, so accelerating gully erosion instead of preventing it. This induced widespread disenchantment amongst local people for all conservation projects that followed (Reij, 1988). Such attitudes remain a critical constraint for many current soil conservation efforts.

Elements of Sustainable and Participatory Soil and Water Conservation Programmes

A brief summary of impacts

By most performance measures, conventional conservation programmes have been remarkable failures. Little has changed over the course of this century. Large sums of money have been spent in the name of environmental protection encouraging and coercing farmers to adopt conservation measures, but poor implementation by outside technical teams means that few structures persist, so causing erosion rather than preventing it. The result has been widespread discrediting of conservation projects and programmes in the eyes of the rural people themselves. However, the issue and costs of soil erosion will not go away. The challenge remains enormous.

There is now emerging evidence that regenerative and resource-conserving technologies and practices can bring both environmental and economic benefits for farmers and communities (Hinchcliffe et al, 1995; Pretty, 1995a; Shaxson, 1996). Importantly, these breakthroughs have come on fanners' fields and in rural communities. It has long been known that resource-conserving technologies will work in research stations, but somehow they have not been widely adopted by farmers. Now, as a result of agricultural professionals increasingly working with and learning from farmers, new productive options are being developed (Table 16.2).

There are now a growing number of programmes that have been sufficiently successful to suggest the need for application on a much wider scale (Shaxson, 1996). All of these successes have elements in common. Farmers have been a central part of the process of innovation and adaptation of resource-conserving technologies. There has been action by groups and communities at local level, with farmers becoming experts at managing farms as ecosystems, and at collectively managing the watersheds or other resource units of which their farms form a part. There have also been supportive and enabling external government and/or non-government institutions, often working in new partnerships with new participatory

Table 16.2 *Sustainable soil and water conservation highlights*

Australia	More than 2000 community groups involving one third of all Australian farmers are now able to tackle local environmental problems that cannot be solved within a single farm boundary; new forms of collective action are emerging, with farmers trying to be visionary about the future rather than victims of circumstance; these land-care groups are formally linked to existing institutions, including national-level policy makers
Brazil	A government programme, EPAGRI, in Santa Catarina has pioneered the use of more than 60 species of green manures and cover crops through its micro-watershed programme; some 38,000 farmers have been reached, with yields more than doubling and farmers needing less labour for weeding and ploughing
Burkina Faso	A government programme, Projet d'Aménagement de Terroirs et Conservation de Ressources (PATECORE), working with farmers in 240 villages has so improved 10,000ha of unproductive drylands with conservation measures that the average family's food deficit of 645kg $year^{-1}$ at the beginning of the programme has been turned around to a 150kg surplus
Honduras	Green manures and cover crops have so improved organic matter in soils that crop yields have more than tripled for several thousand farmers
India	A wide range of non-government and government initiatives throughout India have led to substantial benefits for local people. New linkages between external agencies and local communities are resulting in the recovery of barren lands, an average doubling of crop yields, increased crop diversity, improved well-water availability, greater social cohesion, alternative forms of credit management by local groups, and the federation of local groups to ensure influence over higher-level institutions and political interests. Notable successes are in Karnataka (by MYRADA), Tamil Nadu (by The Society for People's Education and Economic Change with local government), Rajasthan (by Government of Rajasthan), Uttar Pradesh (by Doon Valley Integrated Watershed Management Programme), Gujarat (by Aga Khan Rural Support Programme) and Maharashtra (by Indo-German Watershed Development Programme)
Kenya	The government is pioneering a participatory approach to soil and water conservation; with the mobilization of communities, some 100,000 farms are now conserved each year, on which there have also been increases in food production, diversification into new enterprises, reduction in resource degradation, and increases in labour demand and land prices
Lesotho and Malawi	The innovative rural action learning areas initiative is building upon the best practices of farmers and linking them to research and extension organizations; new forms of collaboration are emerging between institutions throughout southern Africa, with a particular focus on learning loops to improve performance

Table 16.2 *(continued)*

Philippines	Upland rehabilitation programmes run by the Mag-uugmad Foundation, the Farm Management Institute of the Visayas State College (FARMI) and the International Institute for Rural Reconstruction (IIRR) have shown the value of farmer-based extension systems, in which farmer groups experiment with and spread new technologies, with the result that agricultural yields have more than doubled, soils have been conserved, and local economies regenerated

Sources: GTZ, 1992; Balbarino and Alcober, 1994; Campbell et al, 1994; Cerna et al, 1994; Devavaram, 1994; Fernandez, 1994; Freitas, 1994; Kiara et al, 1994; Krishna, 1994; Shah and Shah, 1994; Hinchcliffe et al, 1995

methodologies, which have reoriented their activities to focus on local needs and capabilities.

Value local knowledge and technologies

Before deciding on the course of action, projects should start with what people know and do well already. The problem with agricultural science and extension is that it has poorly understood the nature of 'indigenous' and rural people's knowledge. For many, what rural people know is assumed to be 'primitive' and 'unscientific', and so formal research and extension must 'transform' what they know in order to 'develop' them. An alternative view is that local knowledge is a valuable and underutilized resource (Chambers et al, 1989; Röling and Engel, 1989; Warren, 1991; Scoones and Thompson, 1994). Within this context, understanding processes of agricultural innovation and experimentation is an important new focus.

It is now well documented that for several thousand years farmers have conserved soil and water to sustain agricultural production in many varied contexts. Across North Africa to the Negev desert, farmers under Roman rule created a settled agriculture that lasted for several hundred years in semi-arid conditions (Evaneri et al, 1971; Barker and Jones, 1982). Elsewhere in Africa and the Middle East, at least 40 different indigenous systems of soil and water conservation have been recorded (Reij, 1991; IFAD, 1992; Critchley et al, 1994).

A major problem is that professionals disregard indigenous knowledge and technologies all too easily. In Niger, traditional stone lines in the Ader Doutchi Maggia can be observed by anyone driving on the main road from Konni to Tahoua (Reij, 1991). Despite the presence of conservation projects in the region since the early 1960s and visits by many 'experts', no reports contain reference to these stone lines. In both Niger and Burkina Faso, farmers prefer stone lines and bunds, yet all major projects have constructed only earth bunds, which of course have not been maintained by local 'beneficiaries' (Reij, 1991).

In the medium to high rainfall red-soil areas of Andhra Pradesh and Karnataka, the government recommends graded bunds and contour farming for soil and moisture conservation. Farmers, however, use a diverse mix of technologies, including field boundary bunds and drains with waste weirs, grasses on field bunds and drains, short-term fallowing, criss-cross ploughing, seeding across slope, tied ridging, frequent interculture, deep ploughing in summer, and compartmental bunding (Kerr and Sanghi, 1992).

One example of soil and water conservation measures used widely by farmers, yet commonly ignored by professionals, are silt traps and gully fields. Stones are placed across gullies or valleys to capture nutrients, silt and moisture. The principle is to capture run-off from a broad catchment area and concentrate it in a reduced area, so transforming meagre rainfall into utilizable soil moisture. As water slows, any suspended debris is deposited, helping to form organic-rich soils. These gully or deposition fields have been recorded in India (Chambers, 1991; Shah et al, 1991; Prem Kumar, 1994); Pakistan (personal observations (1992, 1994, 1995) in Punjab and northwest Frontier Provinces), Ethiopia (ERCS/IIED, 1988); Mexico, known as *atajadizos*, *trincheras* and *trancas* (Johnson, 1979; Blackler, 1994); Nepal (Tamang, 1993); and Burkina Faso (Reij, 1988).

A well-maintained silt trap creates a flat, fertile and moist field with a micro-environment quite unlike the surrounding area. Crops can thus be grown which may be of higher value than field crops on nearby drylands, such as rice in India, wheat and rapeseed in Pakistan, sorghum and rice in Burkina Faso, and *chat* and coffee in Ethiopia. Agriculture in these gully fields is productive and dependable (Griffin and Dennis, 1969; Shah et al, 1991). In Burkina Faso, sorghum yields can range between 970 and 2670kg ha^{-1}, and in some fields rice can be grown (Reij, 1988). Farmers in Gujarat have been able to grow high-yielding varieties of lowland paddy, and in some cases achieve yields higher than irrigated regions in dryland areas (Shah, 1994). Farmers additionally benefit from these traps as groundwater levels are raised and damage to crops on the downstream side is reduced (Johnson, 1979; Reij, 1988).

The key element is that these technologies are intrinsically incremental systems, in which farmers add to the height of their structures year by year. Stones are often bedded into the upper surface of spillway aprons and walls to provide support for the next layer, in order to keep the wall above the level of the accumulating alluvium. Wilken (1987) reports the narrative account of an Otomí farmer of Hidalgo, Mexico:

> An *atajadizo* isn't built all at once. Usually a farmer starts with a low wall across the path of an *arroyo* (gully). It takes a few years until the water has brought down enough debris and soil to level with the top of the wall. Then, the farmer will build up the wall a bit more, and so on, little by little until s(he) has built up a tall strong wall and a large level field. A well-made *atajadizo* is level so that the trapped water will cover all parts of the field evenly. It may be necessary to level the field by hand and, also, to tear down parts of the gully in order to enlarge the field. A well-made *atajadizo* always has a wall that is higher than the field behind it. This is necessary because water must be trapped so that it can soak into the field … There is no need to fertilize an *atajadizo* because every rainy season the water brings down new debris and soil.

Enhance farmers' capacity to innovate

It is important to seek and encourage the involvement of farmers in adapting technologies to their local conditions. This is a reversal of the normal modes of research and technology generation, as it requires interactive participation between professionals and farmers. Participatory technology development is a process in which the knowledge and research capacities of farmers are joined with those of scientific institutions, whilst at the same time strengthening local capacities to experiment and innovate (Reijntjes et al, 1992). Farmers are encouraged to generate and evaluate indigenous technologies and to choose and adapt external ones on the basis of their own knowledge and value systems.

Important evidence comes from a variety of soil conservation and agricultural regeneration programmes in Central America (Bunch and López, 1994). The Guinope (1981–1989) and Cantarranas (1987–1991) programmes in Honduras and the San Martin Jilotepeque (1972–1979) programme in Guatemala were collaborative efforts between World Neighbors and other local agencies. They all began with a focus on soil conservation in areas where maize yields were very low (400–660kg ha^{-1}), and where shifting cultivation, malnutrition and outmigration prevailed. All show the importance of developing resource-conserving practices in partnership with local people.

There were several common elements. All forms of paternalism were avoided, including giving things away, subsidising farmer activities or inputs, or doing anything for local people. Each started slowly and on a small scale, so that local people could meaningfully participate in planning and implementation. They used technologies such as green manures, cover crops, contour grass strips, in-row tillage, rock bunds and animal manures that were appropriate to the local area, and which were finely tuned through experimentation by and with farmers. Extension and training was done largely by villager farmers who had already experienced success with the technologies on their own farms.

There are few published studies that give evidence of impacts some years after the outside interventions ended. In 1994, however, staff of the Honduran organization COSECHA (Associatión de Consejeros una Agricultura Sostenible, Ecológica y Humana) returned to the programme areas and used participatory methods with local communities to evaluate subsequent changes (Bunch and López, 1994). The first major finding was that crop yields and adoption of conserving technologies had continued to grow since project termination (Table 16.3). Surprisingly, though, many of the technologies known to be 'successful' during the project had been superseded by new practices. Had the original technologies been poorly selected? It would appear not, as many that had been dropped by farmers are very successful elsewhere. The explanation would appear to be that changing external and internal circumstances, such as changing markets, droughts, diseases, insect pests, land tenure, labour availability, political disruptions and so on, had reduced or eliminated their usefulness.

Altogether, some 80–90 successful innovations were documented in these 12 villages (not counting the failures). There had been innovations in virtually all the

Table 16.3 *Changes in adoption of resource-conserving technologies, maize yields and migration patterns in three programmes in Central America during and after projects*

	At initiation	*At termination*	*In 1994*
No. of farmers with technologies (and no. of villages with technology)

Guinope: 3 villages	38	0	(2)
Cantarranas: 3 villages	nd	10	(6)

Note: 12 villages sampled from the total of 121 in the three programme areas; (2) and (6) indicate in-migration of families; nd = no data.

Source: Bunch and López, 1994

villages. In one Honduran village, Pacayas, there had been 16 innovations since termination, including four new crops, two new green manures, two new species of grass for contour barriers in vegetables, chicken pens made of king grass, marigolds for nematode control, use of lablab and velvet bean as cattle and chicken feed, nutrient recycling into fishponds, human wastes in composting latrines, napier grass to stabilize cliffs, and home-made sprinklers for irrigation.

Technologies had been developed, adopted, adapted and dropped. The study concluded that the half-life of a successful technology in these project areas is 6 years. Quite clearly the technologies themselves are not sustainable. As Bunch and López (1994) have put it 'what needs to be made sustainable is the process of innovation itself'.

A similar picture has emerged in Gujarat, where many farmers have developed new technical innovations after support for undertaking simple treatment measures on their own land. Farmers have introduced planting of grafted mango trees and bamboo near embankments, so making full use of residual moisture near gully traps. They have also introduced cultivation of vegetables, such as brinjal and lady's finger, other leguminous crops and tobacco in the newly created silt traps. This has increased production substantially, particularly in poor rainfall years, as well as diversifying production. Most of these innovations and adaptations have been introduced and sustained with support from the local network of village extensionists (Shah, 1994).

Build up and strengthen local institutions

The success of sustainable soil conservation depends not just on the motivations, skills and knowledge of individual farmers, but on action taken by local groups or communities as a whole. Yet throughout the history of agricultural development, it has been rare for the importance of local groups and institutions to be recognized. Development professionals have tended to be preoccupied with the individual, assuming that the most important decisions affecting behaviour are made at this level. As a result, the effectiveness of local groups and institutions has been widely undermined. Some have struggled on. Many others have disappeared entirely.

Studies of agricultural development initiatives increasingly show that people who are already well organized, or who are encouraged to form groups, and whose knowledge is sought and incorporated during planning and implementation, are more likely to continue activities after project completion. If people have responsibility, feel ownership and are committed, then there is likely to be sustained change.

The process of establishing self-reliant groups at local level must be an organic one (Ostrom, 1990; Röling, 1994). In the early stages, groups focus on establishing agreed rules for management and decision making. These can then be used by members as a vehicle to channel information or loans to individual members. Confidence grows once small homogeneous groups have successfully achieved initial goals, such as the conservation of a hillside. It is then common for members to turn their attention to development activities that will benefit themselves as well as the community at large. This may involve the nomination of individuals to receive specialized training, such as in soil and water conservation, pest control, veterinary practice, horticulture or book-keeping, so that they will be able to pass knowledge back to the whole group in their new role as paraprofessional or extension volunteer (Shah and Shah, 1994; Pretty, 1995a). Alternative institutional mechanisms such as farmer-to-farmer extension and village-managed extension systems have helped to scale up soil and water conservation effectively.

As confidence grows with success, and resource bases expand and group activity can evolve to an entrepreneurial stage where common action projects are initiated. These are held under group ownership and might comprise investing in fruit orchards, afforesting an upper watershed, terracing a hillside, investing in agricultural tools and draught animals for hire to the community, community pest management, organizing community-run wildlife utilization schemes, and building housing for poor families (Murphree, 1993; Fernandez, 1994; Shah and Shah, 1994). These group activities benefit group members as well as having a wider ecological and social impact, and become the mechanism for sustained conservation activity. Local institutions help to mobilize local resources, particularly savings to get access to credit and undertake joint marketing of agricultural produce (Fernandez, 1994; Shah, 1994).

Adopt participatory methods in soil conservation programmes

There is a long history of participation in agricultural development, and a wide range of development agencies, both national and international, have attempted to involve people in some aspect of planning and implementation. In recent years, there have been an increasing number of comparative studies of development projects showing that 'participation' is one of the critical components of success. It has been associated with increased mobilization of stakeholder ownership of policies and projects, greater efficiency, understanding and social cohesion, more cost-effective services, greater transparency and accountability, increased empowering of the poor and disadvantaged, and strengthened capacity of people to learn and act (Reij, 1988; Finsterbusch and Wicklen, 1989; Bagadion and Korten, 1991; Cernea, 1991; Guijt, 1991; Pretty and Sandbrook, 1991; Uphoff, 1992; Narayan, 1993; Scoones and Thompson, 1994; World Bank, 1994; Pretty, 1995a, 1995b; Thompson, 1995).

As a result, the terms 'people's participation' and 'popular participation' are now part of the normal language of many development agencies (Adnan et al, 1992; Rahnema, 1992; World Bank, 1994). However, it has become such a fashion that almost everyone says that participation is part of their work. This has created many paradoxes. The term 'participation' has been used to justify the extension of control of the state as well as to build local capacity and self-reliance; it has been used to justify external decisions as well as to devolve power and decision making away from external agencies; it has been used for data collection as well as for interactive analysis.

In conventional soil conservation projects, participation has commonly centred on encouraging local people to sell their labour in return for food, cash or materials. Yet these material incentives create dependencies and give the misleading impression that local people are supportive of externally driven initiatives. This paternalism undermines sustainability goals and produces impacts which rarely persist once the project ceases (Bunch, 1983; Reij, 1988; Kerr, 1994; Pretty and Shah, 1994).

The many ways that development organizations interpret and use the term participation can be resolved into seven clear types. These range from manipulative and passive participation, where people are told what is to happen and act out predetermined roles, to self-mobilization, where people take initiatives largely independent of external institutions (Table 16.4). This typology suggests that the term 'participation' should not be accepted without appropriate clarification. The problem with participation as used in Types 1–4 is that any achievements are likely to have no positive lasting effect on people's lives. The term participation can be used, knowing it will not lead to action. Indeed, some suggest that the manipulation

Table 16.4 *A typology of participation: How people participate in development programmes and projects*

Typology	*Characteristics of each type*
1. Manipulative participation	Participation is simply a pretence, with 'people's' representatives on official boards who are unelected and have no power
2. Passive participation	People participate by being told what has been decided or has already happened. This involves unilateral announcements by an administration or project management without listening to people's responses. The information being shared belongs only to external professionals
3. Participation by consultation	People participate by being consulted or by answering questions. External agents define problems and information-gathering processes, and so control analysis. Such a consultative process does not concede any share in decision making, and professionals are under no obligation to take on board people's views
4. Participation for material incentives	People participate by contributing resources, for example labour, in return for food, cash or other material incentives. Farmers may provide the fields and labour, but are involved in neither experimentation nor the process of learning. It is very common to find this called participation, yet people have no stake in prolonging technologies or practices when the incentives end
5. Functional participation	Participation seen by external agencies as a means to achieve project goals, especially reduced costs. People may participate by forming groups to meet predetermined objectives related to the project. Such involvement may be interactive and involve shared decision making, but tends to arise only after major decisions have already been made by external agents. At worst, local people may still only be coopted to serve external goals
6. Interactive participation	People participate in joint analysis, development of action plans and formation or strengthening of local institutions. Participation is seen as a right, not just the means to achieve project goals. The process involves interdisciplinary methodologies that seek multiple perspectives and make use of systemic and structured learning processes. As groups take control over local decisions and determine how available resources are used, so they have a stake in maintaining structures or practices
7. Self-mobilization	People participate by taking initiatives to change systems independently of external institutions. They develop contacts with external institutions for the resources and technical advice they need, but retain control over how resources are used. Self-mobilization can spread if governments and NGOs provide an enabling framework of support. Such self-initiated mobilization may or may not challenge existing distributions of wealth and power

Source: Pretty, 1995a

that is often central to Types 1–4 means they should be seen as types of non-participation (Hart, 1992; Satterthwaite et al, 1995).

Great care must therefore be taken over both using and interpreting the term participation. It should always be qualified by reference to the type of participation, as most types will threaten rather than support the goals of sustainable agriculture. What is important is to ensure that those using the term participation both clarify their specific application and define better ways of shifting from the more common passive, consultative and incentive-driven participation towards the interactive end of the spectrum.

In recent years, the creative ingenuity of practitioners worldwide has hugely increased the range of participatory methods and approaches in use (see Conway, 1987; KKU, 1987; *PLA (formerly RRA) Notes*, 1988 cont.; Mascarenhas et al, 1991; Chambers, 1992; IDS/IIED, 1994; Pretty et al, 1995). These imply shifts of initiative, responsibility and action to rural people themselves, and result in processes of collective learning leading to collective action. Sustainable soil and water conservation, with all its uncertainties and complexities, cannot be envisaged without all stakeholders being involved in continuing processes of learning and action.

Future Challenges: Towards Land Husbandry

Soil and water conservation practices based on imposed technological interventions have not delivered the environmental or economic benefits they promised. The practice of designing and implementing interventions without involving local people can only succeed with coercion. Such enforced responses may appear technically appropriate, but are commonly rejected by local people when external pressure is removed.

A thorough reassessment of existing soil and water conservation practices is needed, building on the recent experiences of participatory and farmer-oriented programmes that emphasize the broader goals of land husbandry. These experiences signal that changes to soil and water conservation programmes are both possible and positive. The principal impacts have been:

- economic benefits, such as increases in land value and demand for labour, substantial increases in crop and livestock production, and increases in fodder and fuel production, increases in the diversity of crops grown, and improvements in livelihood security through the diversification of livelihood sources;
- social benefits, such as greater self-confidence and sense of cohesion in communities, reduced conflicts over resources, reduced out-migration, attention to the needs of landless groups and new rapport between local people and external professionals;
- environmental benefits, such as recharge of aquifers and increased supply of drinking and irrigation water, reduced soil erosion, salinity, and the use of

fertilizers and pesticides, increased numbers of trees, birds and other wildlife.

Despite the differences in cultural, political and bio-physical contexts, there are important common elements. All emphasize the use of locally adapted resource-conserving technologies that provide immediate returns to farmers, rather than the use of externally derived technologies. All focus on encouraging action by groups or communities at local level, rather than working with individual farmers. All involve supportive government and/or non-government institutions working in partnership with each other and with farmers.

As conditions and knowledge change, so farmers and communities must be encouraged and allowed to change and adapt also. Sustainable soil and water conservation must not impose models or packages. Rather, it should become a process for learning and perpetual novelty.

The challenge now is to identify and encourage the conditions that will foster the further spread of these innovative efforts. Most of these are still only islands of success. This is partly because favourable policy environments are missing. Most agricultural policies still actively discriminate against sustainability. Existing policy frameworks are now one of the principal barriers to the spread of a more sustainable and productive agriculture, and this is where future changes will be essential.

Acknowledgements

This paper is one output from the research project *New Horizons: The Economic, Social and Environmental Impacts of Participatory Watershed Development*. This was a 2-year programme of research support and institutional collaboration between the Sustainable Agriculture Programme of IIED and partner institutions in Asia, Africa, Latin America and Australia. The project was funded by the Swedish International Development Cooperation Agency (SIDA), the Swiss Development Cooperation (SDC), the Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ), the Ford Foundation, the British Overseas Development Administration, and the Australian International Development Assistance Bureau (AIDAB – now AusAID).

The authors are grateful for helpful comments on earlier versions of this paper by participants at the November 1994 joint IIED/ActionAid conference in Bangalore, together with those of two anonymous referees. Any errors and omissions are, of course, the sole responsibility of the authors.

Rethinking Agriculture for New Opportunities

Erick Fernandes, Alice Pell and Norman Uphoff

Over the last 30 years, the creation and exploitation of new genetic potentials of cereal crops, leading to what is called the Green Revolution, has saved hundreds of millions of people around the world from extreme hunger and malnutrition, and tens of millions from starvation. However, these technologies for improving crop yields have not been maintaining their momentum. The rate of yield increase for cereals worldwide – around 2.4 per cent in the 1970s and 2 per cent in the 1980s – was only about 1 per cent in the 1990s. Although the global food production system has performed well in recent decades, will further support of conventional agricultural research and extension programmes increase yields sufficiently to meet anticipated demand?

The next doubling of food production will have to be accomplished with less land per capita and with less water than is available now (Postel, 1996). The gains needed in the productive use of land and water are so great that both genetic improvements and changes in management will be required. The world needs continuing advances on the genetic front; however, food production is more often limited by environmental conditions and resource constraints than by genetic potential. Preoccupation with the methods that brought us the Green Revolution can divert attention from opportunities that can increase food supply without adversely affecting the environment, which are considered in this book.

Given appropriate research, policies, institutions and support, food production could be doubled with the existing genetic bases. Many of the needed advances in food production could be achieved by developing agricultural systems that capitalize more systematically on biological and agroecological dynamics rather than by relying so much on agrochemicals, mechanical and petrochemical energy and genetic modification.[1] This will require, however, some rethinking of what constitutes agriculture.

Although it has been argued that agricultural output will decline if 'modern' agriculture is not promoted to the maximum (e.g. Avery, 1995), 'lowtech'

Reprinted from Fernandes E, Pell A and Uphoff N. 2002. Rethinking agriculture for new opportunities, in Uphoff N (ed) *Agroecological Innovations*, Earthscan, London, pp21–39.

methods can be very productive with now-better-understood scientific bases. Where economically justifiable, these methods use available resources more efficiently than do high-input approaches.

The potential of non-mainstream methods cannot be known until agroecological approaches are taken more seriously and evaluated systematically. Gains made through genetic improvement and use of external capital and chemical inputs over the last four decades have been substantial, and the first Green Revolution, despite the shortcomings some critics have pointed to, was one of the major accomplishments of the century.[2] But what will agricultural science do for an encore? While biotechnology holds out many promises, most of its benefits continue to be anticipated more than realized. Access to and widespread distribution of biotechnology's prospective benefits remain uncertain. The widely publicized 'golden rice' is still years from production in farmers' fields.

The challenge facing agriculture worldwide involves more than just achieving higher production, justifiable as that goal has been for previous scientific innovation when serious food deficits were an ominous possibility. Valid ecological and social considerations now make it imperative that further advances be environmentally friendly as well as economically sustainable and socially equitable. Also, more than increased food supply is needed; we should aim to ensure balanced and adequate supplies of nutrients that people can afford. In particular, adverse environmental and health externalities that result from modern agricultural methods – soil erosion, chemical hazards, soil and water pollution – are things that nobody would like to see increased, let alone doubled, as we seek to double the production of food.

Should resources for agricultural research be devoted, for example, to developing genetically engineered rice with high levels of vitamin A, assuming that cereal grain monoculture will continue to predominate? Or should we strive to incorporate nitrogen-fixing and nutrient-rich legumes and livestock into farming systems to better meet people's nutritional requirements with diversified diets – while simultaneously maintaining soil fertility? Such questions need to be addressed.

The next Green Revolution will depend at least in part on enlarging upon and diversifying the ideas that have guided past development efforts. The paradigms that presently organize and direct agricultural research and extension have been helpful for planning activities and producing theoretical explanations. But they have also created certain blind spots. The task of meeting world food needs will be more difficult if our vision of what is possible is limited by constraining conceptions of how best to raise agricultural output in effective, efficient and sustainable ways.

Agriculture as Field-culture: An Etymological Perspective

The very concept of agriculture as it has been understood and practised in the West has been shaped by its semantic origins, coming from the Latin word ager, 'field'. Agriculture is mostly understood as the growing of plants in fields. (Similarly, in

South Asia, most words for agriculture derive from the Sanskrit word for plough, *krsi*, so that agriculture in that region is characterized as 'plough work'.) Such a conceptualization, however tacit, makes the raising of livestock, fish, trees and other activities less central to the agricultural enterprise, except where cattle or oxen are necessary for ploughing, or where monocrop tree plantations substitute for fields. The full range and richness of the agricultural enterprise has not been well captured in the word that we use to refer to it.

Etymologically, it is not clear where livestock, fish, insects, microbes and trees fit in. Few sustainable farming systems exist that do not include several of these groups in addition to plants. But most often, those who work on other flora or on fauna have been accorded marginal status within agricultural ministries, or been assigned to separate ministries, leaving crop and soil specialists in charge of the agricultural sector.

Fishery departments are invariably marginal if located within an agricultural ministry, even though aquaculture integrated within farming systems has great potential. Indeed, until 'agroforestry' was discovered (King, 1968; Bene et al, 1977) and the International Centre for Research in Agroforestry (ICRAF) was established, there was little concern with trees as part of agriculture, except in large-scale plantations where tree crops were commercially profitable. Otherwise, trees got respect and attention only if looked after by a separate ministry that was more concerned with forests or plantations than with farms.

Although *agroforestry* may sound like a kind of forest management, it is a comprehensive land-use management strategy that includes a range of woody perennials (particularly trees but also shrubs) in spatial and temporal associations with non-woody perennials, grasses and annual crops, together with a variety of animals, including cattle, sheep, goats, pigs, chickens, guinea pigs, fish and even bees (Lundgren and Raintree, 1982). While some agroforestry practices are extensive – for example, most agrosilvopastoral systems – these practices generally contribute to intensified production that is agroecologically sound and maintains soil fertility (Fernandes and Matos, 1995). Fortunately, the integration of perennial plants into otherwise annual farming systems is increasingly recognized as a mainstream opportunity to increase per-hectare output in future decades.

A bias in favour of fields means that horticulture gets somewhat marginalized in most institutions dealing with agriculture, including universities. Gardens and orchards, being smaller, have lower status than fields, even if they produce several times more value per unit of land when intensively managed. Horticulture is devalued in part also because its produce is mostly perishable and hard to denominate. Heads of cabbage and baskets of apples are hard to compare with bags of rice or tons of wheat, their nutritional value notwithstanding. Historically, governments have gained more wealth and security from grains because these could be stored (or seized) more easily than fruits and vegetables.

Farming systems of most rural households around the world depend crucially upon livestock and poultry, large and/or small, together with home gardens and orchards and often with fish ponds and hedgerows. Efforts to improve single components of farming systems are likely to produce limited results unless the interdependence of land use, labour supply and seasonal activities for all of these farm enterprises is acknowledged.[3] In many areas of Asia, acceptance of the short-stalked, high-yielding cereal varieties that made the Green Revolution was low, for example, because the quantity and quality of the fodder produced by the new varieties was insufficient to meet livestock requirements. The goal of plant breeders had been to increase grain yield without considering forage needs. Farmers were willing to accept lower yields of grain in order to be able to feed their animals, which provided them with the manure they needed to maintain soil fertility and the traction required for tilling their land.

An argument sometimes made against livestock production is that animals are inherently wasteful; more calories can be produced per hectare from plants than from animals. If animals are fed on forages and by-products, however, rather than competing with humans for edible grain, such 'wastefulness' can be beneficial. In extensive and semi-extensive systems, animals that range freely during the day harvest plant nutrients from non-arable areas; at night when they are penned, most of these nutrients are deposited in their enclosure, later to be distributed as manure onto cropland. In parts of West Africa, pastoralists often negotiate grazing contracts with crop-growing neighbours. Pastoralists are encouraged to graze their cattle on fields with crop residues because the cattle deposit manure: their owners may even receive additional compensation for this service. If animals were in fact highly efficient in their conversion of harvested nutrients, there would be less transfer of nutrients from rangelands to croplands.

When green and animal manures are judiciously used in combination, nutrient availability can be nicely synchronized to meet plant demands. Manure is an important product of livestock raising. In sub-Saharan Africa, 25 per cent of agricultural domestic product comes from livestock even without considering manure or traction; when these are considered, this figure rises to 35 per cent (Winrock International, 1992). The quality and quantity of manure produced depends on what the animal consumes; in Java where 'cut and carry' tree-based fodder systems are common, animals are given extra feed to improve the quality of their manure (Somda et al, 1970; Tanner et al, 1995). Thus, animal production can be beneficial in ecological as well as human nutritional terms.

An additional consideration obscured by a preoccupation with fields is that common property resources for grazing and for forest products are an essential part of many households' economic operations (Berkes, 1989; Jodha, 1992).

Common lands are often the sites from which grazing livestock harvest nutrients that are brought back to the farm at night. As these areas are not fields, however, and do not belong to any specific user, evaluating their contributions to production is admittedly difficult. This is not, however, sufficient reason to overlook their role and potential, leaving their productivity to languish.[4] Privatization of these commons, often advised, removes the flexibility people need to withstand drought in dry regions. Farming systems improvement should encompass all the area and resources available to farmers and pastoralists.

Developing an adequate knowledge base for more productive and sustainable agriculture should start with explicit acknowledgement that agriculture involves much more than fields and field crops. To be sure, fields are commonly the main component of most farm production strategies. *Staple foods* are, after all, what their name implies – essential for food security. The world in general needs more, rather than less, of them, especially for the 800 million people who are currently undernourished. But other sources of calories are also important – potatoes, cassava, yams, sorghum, millet, sweet potatoes, taro, fish, meat, milk and so on – and these have been given much less support than rice, wheat and maize.[5] Calories, while necessary for survival, are not sufficient for human health. To achieve balanced diets, including essential micronutrients, the whole complex of flora and fauna that rural households manage to achieve food security and maintain their living standards should be better understood and utilized.

Not only should fixation on individual crops be avoided, but a broader understanding of the biophysical unit for agriculture is needed. A narrow focus on fields is giving way to a broader focus on *landscapes* and/or *watersheds*, within which fields function as interdependent units, especially as we gain a better agro-ecological understanding of agriculture (Carrol et al, 1990; Altieri, 1995; Conway, 1997).

Assumptions Associated with Field-centred Agriculture

Several limitations arise from this long-standing concept of agriculture. In different ways, each works against strategies for intensified and sustainable agricultural development that use the full set of local resources most productively.

The time dimension of agriculture: A cyclical view

In lore and literature, agriculture is described and celebrated as 'the cycle of the seasons'. How is agriculture practised with its field-based definition? By ploughing, planting, weeding, protecting and finally harvesting. Farmers then wait until the next growing season to plough, plant, weed, protect and harvest again, and wait once more for the next planting time. Planting defines agriculture in our minds as does the activity of harvesting. Yet if one looks beyond this standardized seasonal conception of agriculture, one finds trees that keep their leaves year-round, sheep that lamb twice a year, and microbes that continuously decompose soil organic matter with generation intervals measured in hours or minutes. These different time frames all affect agricultural performance.

Fixation on an annual cycle of agriculture has arisen from its practice in temperate climates, where most modern scientific advances have been made. There, summer and winter seasons are the central fact of agricultural life. The year-round agriculture of tropical zones seems somehow irregular, almost unnatural, since it lacks periodic cultivation. This view is reflected in reports from early colonial administrators in tropical countries who regarded indigenous populations as 'lazy' because they did not work hard to produce their sustenance. There was no annual cycle of ploughing, planting and so on, which counterparts in colder climates had to maintain. People who harvested what they had not planted, or had not planted recently, were not regarded as 'real agriculturalists' by people from temperate zones.

There is seasonality in tropical regions, to be sure. The contrast between wet and dry seasons can be as stark as that between summer and winter. But with agriculture seen primarily as a matter of *cultivation*, annual crops get more attention and status than perennials. The latter have very important roles to play, however, particularly if one is concerned with the sustainability of agriculture. Their growth usually does not disturb or tax the soil as much, or as often, as does annual cropping. The latter invests in myriad biological 'factories' that produce food or fibre and then demolishes them at the end of the season. On the other hand, trees, vines or crops that ratoon keep all or most of that biological factory intact from year to year.

Since, usually, very little biomass is discarded in the farming systems operated by poorer farm families – it is used for fodder, fuel, mulch or other purposes – our point here is directed to research and extension priorities rather than to farmers. The latter have long known that combining a variety of perennials with annuals, animals and horticultural crops creates opportunities for more total output from given areas of land during the year, and with less pressure on soil resources; energy and nutrient flows are more efficient, and adverse pest and environmental impacts can be reduced by growing perennials rather than annuals.[6] Especially if the sustainability of agricultural production is an objective, giving perennials a larger role in agriculture makes sense.

Within agriculture understood in annualist terms, fallows are periods of rest and recuperation for the soil, a kind of gap in the cropping calendar. Many farmers, however, have thought of fallows differently, managing them so that they are more productive than land that is simply left alone. 'Managed fallows' are not an oxymoron but rather a source of supplementary income, providing fodder, fruit or other benefits while enriching the soil when leguminous species or plants otherwise considered to be weeds are allowed or encouraged to grow.[7] Cropping cycles are best looked at in terms of how soil fertility can be continuously enhanced while utilizing a wide variety of plant and animal species – a strategy described as 'permaculture' by Mollison (1990) – looking beyond crops that are planted periodically.

Spatial dimensions of agriculture: Thinking in terms of soil volume instead of surface

Agriculture has been defined and limited by a mental construction of agricultural space in much the same way that it has been stereotyped in terms of annual cycles.

While farmers have long appreciated that agriculture is an enterprise best conducted in three dimensions, most agronomic and economic assessments consider agriculture essentially in *two dimensions*, as an enterprise carried out on a plane. The practice of agriculture is epitomized by ploughing, which breaks the surface of the soil in order to plant seeds and grow crops. This strategy suffices so long as the soil is deep, fertile and well supplied with water. But agriculture can be made more productive by conceiving and treating soil in *three-dimensional* terms, as volume, doing more than just breaking its surface and working it two-dimensionally.

Indeed, working the soil is a better term for agriculture than ploughing it, since working encompasses many functions.[8] This concept includes incorporating organic matter of various sorts into the soil and altering soil topography to capture and hold water, or to drain it. Getting crop residues and animal manures into the soil can promote greater synchrony between nutrient release from those residues and crop nutrient demand; soil organic matter promotes better water infiltration and retention at the same time that it creates better habitats for soil microflora and for micro- and macrofauna. In many traditional farming systems around the world, one finds soil being mounded into raised beds and even raised fields; terraces are constructed to retain and improve the soil and to make watering it easier, and drains are often installed. Soil-working activities are intended not just to exploit the soil's fertility but to improve it.

Alternately, in some farming systems one finds no ploughing, just the planting of seeds in undisturbed soil. This might be considered one-dimensional agriculture with activities concentrated on points rather than a surface, leaving the volume of soil beneath intact to nurture macro- and microbiological communities. To be sure, two-dimensional thinking accomplishes some important activities such as weed control and breaking the soil crust, but disturbances of the soil contribute to major erosional losses. Weeds can be controlled by other means than ploughing, and 'no-till agriculture' is now widely accepted as a modern practice, as noted below.

In the coming decades, efforts to raise yields per hectare should not take the quality and durability of soil for granted, as the health and fertility of the soil are critical for productive and sustainable agriculture. Soil should be understood and managed in terms of its *volume* rather than its *surface*. Raising output sustainably will require more than working chemical fertilizers into the top horizon. Thinking of soil three-dimensionally should be part of any strategy for sustainable agricultural intensification.

Monoculture as 'real' agriculture

The standard view of agriculture as limited in time and space favours monocropping for achieving control and efficiency in production. Applying inputs is made easier with monoculture, whether calculating fertilizer applications or using mechanical power for weeding. But the conclusion that this is always the most productive way to use land is mistaken. This production method can raise the economic returns to labour or to capital, but it does not necessarily increase the returns to land. The latter resource will become ever more important in coming decades as the availability of arable land per capita declines.

Polyculture systems employing a combination or even a multitude of plants commonly have higher total yields per hectare, absorbing and generally requiring higher inputs of labour and nutrients. Where labour is relatively abundant and land is relatively scarce, this can be an efficient and economic system of resource use. The advantage of monocropping is that it makes mechanization, substituting capital for labour, more effective.[9] Only where mechanical power can bring into cultivation land that manual power cannot is greater physical production likely to result from mechanization. This generally makes agriculture more extensive than intensive.

Even when population is high in relation to arable area, it can be difficult to attract or retain labour to work in farm operations. Much of the impetus for farm mechanization has come from labour scarcities in the more economically advanced countries. When tractors and other machines have been introduced into developing countries with the mistaken idea that this will raise production, they have done more to displace labour than to make land more productive. Tractorization can raise profits for those who have greater access to land and capital, but it seldom leads to higher output per unit of land than using hand labour and animal traction, other things being equal.[10] In contrast to tractors, animals used for traction reproduce themselves, pay returns on the farmer's investment, and provide food, fuel and fertilizer at the same time. Since capital is so often subsidized by government policies, one should not consider the private profitability of using tractors and other capital inputs as a sole or sufficient justification for their use without analysing the full range of social costs and benefits.[11]

Because polyculture is less amenable to mechanization, it requires an adequate and reasonably skilled supply of labour. Many of the practices we discuss here are relatively labour-demanding, using human energy and skill instead of capital and chemicals to get more production from limited land resources. To the extent that investments of labour are made more productive by agroecological innovations, they can be better remunerated and lead to improvements in the agricultural sector and the rest of the economy.

It is widely believed, with more emotion than calculation, that clean-ploughed fields, sown uniformly in a single crop, planted neatly in rows with all extraneous plants removed, is the best kind of agriculture. Mulch makes fields look messy, and crop mixtures look chaotic rather than productive. But this assessment is more a matter of aesthetics than of science. Yields, yield stability and nutritional quality per unit of land from polyculture, although harder to measure, are usually greater than with monoculture.[12] Furthermore, keeping soils covered protects them against erosion.

Polycropping supported by a strategy of managing and recycling organic inputs offers many advantages and can raise yields with equivalent inputs. When maize and soybeans are intercropped, for example, there is about a 15 per cent gain in production that cannot be explained simply by the inputs applied, an increase reflecting synergy within the crops' growing environments (Vandermeer, 1989). Plant–animal intercropping yields comparable benefits. There are many situations, determined more by economic than by agronomic considerations, where monoculture will be a preferable strategy. But its superiority should not be assumed without proof, as happens now.

Mechanical conceptions of agriculture

Monocropping implicitly regards agriculture as a mechanical process, with inputs being converted into outputs by some fixed formula, whereas polycropping recognizes the inherently biological nature of agriculture. The relation posited between inputs and outputs is different for mechanical and biological paradigms. In the first, the ratio of outputs to inputs is predictable and proportional, fixed and usually linear. In the realm of nature, on the other hand, relationships are less predictable and seldom proportional. Large investments of inputs can come to nought, while under favourable conditions and with good management, modest inputs have many-times-larger effects.

Until something like the perpetual motion machine is invented, such disproportionality is not possible with mechanical phenomena, which depend on continuous inputs for their operation. Biological processes, on the other hand, can be self-sustaining and can adapt and evolve unassisted. Moreover, biological *inputs* can reproduce themselves. How one regards and utilizes inputs thus differs in subtle but important ways according to whether they are understood within a mechanical framework or in a biological context.

One area where 'modern' agriculture has rediscovered the advantages of biology is with so-called minimum tillage or no-till systems, now given the positive appellation 'conservation tillage' (Avery and Avery, 1996). Twenty years ago this was considered atavistic agriculture, harking back to the dibble stick in a modern era when heavy tractors and field machinery should be used to plough, plant, weed and harvest 'clean' fields. Yet no-till agriculture has now become state-of-the-art in many areas of the US. Mechanical corn harvesters are designed to chop up plant stalks, leaves, husks and cobs to return this biomass to the land in biodegradable form to preserve soil fertility. In addition to recycling nutrients, conservation tillage protects the soil's surface and reduces wind and water erosion. The main limitation with little or no tillage is that weeds can become more of a problem unless farmers can afford chemical herbicides or use hand labour. (This new/old technology has become popular with businesses that sell herbicides to control weeds when there is no ploughing).

Innovative practices like the use of mulches, cover crops and green and animal manures, which were until recently largely ignored in 'modern' agriculture, can solve the problem of weeds. These techniques capitalize on the large dividends that nutrient recycling can pay because of the multiplicative dynamics of biological processes. Whereas mechanical advantage is a well-accepted principle in physics and engineering, agricultural science should capitalize on the analogous and even more powerful principle of *biological advantage*.

Four Equations in Need of Revision

Efforts to raise agricultural productivity have been guided for many decades by four presumptions. These have produced some impressive results, so our objection is not that they are wrong. Rather, they have become too dominant in our thinking, with too hegemonic an influence on policy and practice. It has been taken for granted that they represent superior ways to boost production. This thinking can be stated in four tacit equations that have shaped contemporary agricultural research, extension and investment.

1. Control of pests and diseases = application of pesticides or other agrochemicals.
2. Overcoming soil fertility constraints = application of chemical fertilizers.
3. Solving water problems = construction of irrigation systems.
4. Raising productivity beyond these three methods = genetic modification.

Equating certain kinds of solutions with broad categories of problems limits the search for other methods to solve those problems, even when alternative practices might have a lower cost and be more beneficial in environmental and social terms. More progress in agriculture will be made if the above propositions are broadened. Fortunately, there is a good precedent in the way that the first equation has been substantially modified over the past 15 years.

Crops and animals can be protected by non-chemical means

The modern-input paradigm for raising production has been most directly challenged with regard to pest and disease control through what is called *integrated pest management* (IPM). Adverse effects on human health as well as on the environment caused some scientists to explore ways to produce crops and animals with little and even no use of chemicals. Biological controls as well as alternative crop management practices have often turned out to be more cost-effective, and sometimes simply more effective. The chemical-based strategy of 'zero tolerance' for pests and diseases, rather than being a solution, exacerbates the problem, killing beneficial insects that are predators of crop pests. The widespread use of agrochemicals, particularly broad-spectrum ones, has had the consequence of making pest attacks worse.[13] Routine use of antibiotics to treat diseases and promote the growth of livestock has, unfortunately, increased the antibiotic resistance of pathogens that can infect humans and/or animals.

An IPM strategy does not preclude the use of chemicals. But the first lines of defence against pests and diseases are biological, trying to utilize the defensive and recuperative powers of plants and animals as well as the activity of beneficial and predator insects to farmers' advantage.[14] The Indonesian IPM programme, for example, taught farmers that spiders, previously viewed with antagonism, should be protected and preserved. Demonstrations showed that rice beyond a certain stage can sustain extensive leaf damage from insects, as much as 25 per cent, without depressing effects on yield, and even possibly some gain. When sheep in Australia and South Africa were fed leguminous forages containing tannins as part of their diets, their internal parasite loads were reduced, reducing expenditures on antihelmintic medicines and providing an alternative treatment when antihelmintic resistance is a problem (Kahn and Diaz-Hernandez, 2000). The presumptions of modern agricultural science regarding chemical means for pest and disease control have been broadly challenged, with such means being increasingly reduced and avoided where possible.

Soil fertility can be enhanced, often more effectively, by non-chemical means

The most broadly successful component of modern agriculture has been the introduction and use of inorganic fertilizers to supply soil nutrients, particularly nitrogen, phosphorous and potassium, where these were lacking. But this success has led many policy makers and some scientists to equate soil fertility improvement with the application of fertilizers when, in fact, fertility depends on many additional factors. Indeed, the misuse or overuse of chemical fertilizer results in adverse effects on yield by negatively affecting the physical and biological properties of soil. The advantage of inorganic fertilizers is that they are easier to apply, often cheap (if subsidized) and have more predictable nutrient content. Also, organic nutrients are sometimes simply not available in sufficient supply.

When inorganic fertilizers are added to soils that possess good physical structure, with adequate soil organic matter and sufficient cation-exchange capacity, they can produce impressive improvements in yield. Where soils are acidic (low pH) and the nutrients needed for plants are in short supply, the application of appropriate amounts of lime (calcium carbonate) along with inorganic fertilizers can result in spectacular crop yield increases and can greatly improve farmer income. But in many circumstances, especially in the tropics, soils are not so well structured or well endowed. Then, inorganic fertilizers, especially if used in conjunction with tractors that compact the soil, can lead to changes in soil physics and biology that are counterproductive and diminish, sometimes sharply, the returns from adding chemical nutrients.

We have suggested to dozens of soil scientists in the US and overseas that probably 60–70 per cent of soil research over the past 50 years worldwide has focused on soil chemistry and about 20–30 per cent on soil physics. This means that less than 10 per cent of soil research has been devoted to improving our understanding of its biology. This estimate has not been challenged by agronomists to date. Why such preoccupation with soil chemistry? It is the easiest kind of soil deficiency to study, giving quick, precise and replicable results, which point to simple remedies. The results of soil chemistry analyses are easy to interpret; by adding certain amounts and combinations of fertilizer nutrients, one can expect predictable increments to production. Moreover, such research gets funding easily, given the interests of fertilizer producers in such knowledge.

Yet even brief consideration of these three domains affecting soil fertility suggests that the amount of effort going into each, even if not necessarily equal, should be closer to parity. Any national research programme that deliberately allocated its scientific resources in the above disproportions would be considered misguided. Microbial activity is essential for nutrient availability and uptake. When one walks on ground that has been converted by leguminous species, compost, mulch or manures from something resembling concrete into absorbent, friable soil underfoot with good tilth, the contribution of soil microbiology is self-evident. But studying biological processes is more difficult than assessing differences in soil structure, and many times more difficult than measuring the chemical composition of soil samples.

Similarly, plant scientists with whom we have spoken have agreed that 90 per cent or more of their research effort over the past 50 years has been devoted to those parts of plants that are above ground, and less than 10 per cent to what is below ground. Indeed, plant scientists usually suggest that less than 5 per cent of their research has investigated sub-surface processes and dynamics. Yet any assessment of how plants grow and thrive suggests that a more balanced distribution of effort is desirable, with much more attention paid to the growth and functions of roots than in the past. However, just as it has been easier to study the chemistry of soil, it has been easier to analyse leaves and stalks than to probe the underground mechanisms of roots for uptake and transport of nutrients and water. Changing the soil's temperature by just a few degrees can alter significantly the microbial populations underground, for example, which makes such research difficult to replicate and validate.

Modern agricultural research's focus on soil chemistry and above-ground portions of plants has led to solutions that favour chemical and mechanical means. The belief that chemical fertilizers are the best way to deal with soil fertility limitations has arisen from – and has reinforced – the image of agriculture as a kind of industrial enterprise, where producing desired outputs is mostly a matter of investing certain kinds and amounts of inputs. Consequently, viewing agriculture more as a biological than as a mechanical process attaches greater value to the use of organic inputs. In recent years there has been a major increase in the application of biologically based technologies, such as vermiculture (raising worms) to enhance soil fertility and ameliorate the negative effects of industrial and agricultural wastes on soil (Appelhof et al, 1996; Acharya, 1997).

As in most things, combinations of factors are more likely to approach the optimum than one factor by itself. It is well known that for plants to utilize chemical fertilizer effectively, the soil in their root zone must have substantial capacity to retain and exchange nutrient cations, and that exchange capacity is considerably enhanced as soil organic matter content increases. Research shows the benefits of utilizing organic means to maintain soil fertility and also of adding some inorganic nutrients in combination with organic inputs to get the best results.[15]

Adding appropriate amounts and combinations of chemical nutrients can increase both plant productivity and the amount of crop residues (shoots and roots) that become available to increase and maintain soil organic matter. Augmenting organic matter is especially necessary in tropical soils, which, due to climatic and edaphic conditions, are more likely to need maintenance and restoration of organic material and nutrients. The bottom line is that chemical fertilizers by themselves are no substitute for incorporation of soil organic matter. Ideally both will be used in synergistic ways.[16]

Irrigation is not the only way to deal with water limitations

A mechanistic conception of agriculture reinforces the millennia-old fixation on irrigation as the best if not the only means of providing water for plants in water-scarce environments. In many places, given hydrological cycles and opportunities, irrigation is certainly necessary for the practice of agriculture. But its success over several thousand years has led people to look to this technology as the universal solution to water scarcity problems. When crops need water, the first thought is how to provide irrigation from surface or groundwater sources.

But there are other ways to meet crop requirements besides capturing water in a reservoir, by river diversion or by pumping it from some body of water above or below ground, and then conveying it through canals and other structures to deliver it to particular fields, in amounts and at times when it is needed.[17] In much the same way that assuming soil fertility problems are best solved by fertilizer applications, seeing water shortages as best handled by irrigation has made water harvesting and conservation almost lost arts. When farmers in semi-arid Burkina Faso, assisted by OXFAM, demonstrated that they could grow much better millet crops simply by placing rows of stones across their fields, to slow water runoff and store it in the soil, this was seen as a remarkable technology (Harrison, 1987, pp165–170); numerous case studies with similar results have been documented in Reij et al (1996). Such practices should become part of the repertoire of soil and water management practices that farmers can adopt to utilize available rainfall most advantageously. Using mulch to capture water and slow evaporation is another simple method.

Measures to conserve and utilize water, like planting crops in certain rotations or seeding a new crop in a standing one to capitalize on residual moisture, should not be seen as something novel but rather as something normal, making the best use of water in combination with soil. Methods including collecting and storing water in small catchment dams, large clay jars or simply in porous soils should be experimented with to determine which designs can provide enough water to crops and animals (and for human uses) to justify the expenditure of labour and capital and sometimes land. Small catchment ponds are becoming more attractive and feasible options, providing water supplies in situ. We should also understand better how land preparation practices affect water retention and utilization.[18]

Irrigation will surely remain a major means for solving water problems, and we should be learning how to use scarce irrigation water more efficiently and effectively through social organization (Uphoff, 1986; 1996). But irrigation is not the only means to ensure that growing plants and animals have the water they need. Water scarcity will surely increase for agriculture around the world, so all possible means to acquire and conserve water need to be considered.

Genetic manipulation is not always necessary to raise production significantly

The modern approach to agricultural improvement has stressed better plant and animal breeding, especially since the advent and success of the Green Revolution. Without denying the value of such efforts, or that there will be some future benefits from biotechnology, we think more attention should be paid to cultural practices, to soil preparation and management, to the use of organic inputs, to more productive cropping patterns and systems, and to species that have previously been overlooked or underutilized.

A good example is the system of rice intensification (SRI) developed in Madagascar which can boost yields from any variety of rice by 100–200 per cent or more by changing management practices and without requiring any use of purchased inputs. There are other examples of major yield increase potentials with staple crops. In the 1970s, a programme in Guatemala was able to help farmers raise their maize and bean yields from 400–600kg/ha to about 2400kg in just seven years, at a cost of about US$50 per household. Farmers who had become acquainted with experimentation and evaluation methods proceeded to double yields once more on their own after external assistance was withdrawn. Very poor farmers working with an NGO in the high Andean regions have found that they could double or triple their yields of potatoes and barley by using lupine, a leguminous plant, as a green manure to add nitrogen to the very poor mountain soils and increase soil organic matter. This method, like SRI in Madagascar, works with whatever varieties farmers are already planting and uses organic rather than chemical inputs from outside the community. Leguminous fallows can raise maize yields in southern Africa by two to four times.

The Mukibat technique, named after the farmer who devised it in Indonesia almost 50 years ago, can increase the yield of cassava by five times or more. It involves grafting cassava tubers onto the root of a wild rubber tree of the same genus as cassava, which gives the growing tubers more access to sunlight and nutrients (Foresta et al, 1994). That this technology has aroused so little scientific attention, and was not reported in the literature until more than 20 years after it was devised (Bruijn and Dharmaputra, 1974), may reflect the indifference among most researchers towards cassava, a low-status staple crop on which hundreds of millions of people depend for much of their sustenance. Or perhaps it reflects a lack of interest in innovations that do not come from the scientific community.

Smallholding farmers around the world at present are probably exploiting less than 50 per cent of the existing genetic potential of various crops due to less than optimal management. In many cases this is because the returns to labour are not high enough to justify intensification, but often it is a matter of not knowing how to capitalize on synergies that could raise these returns. Reducing the yield variability of traditional varieties and taking fuller advantage of their genetic potential through nutrient cycling and better soil and water management within complex farming systems could, we think, be a cost-effective strategy that complements longer-run and higher-cost biotechnological efforts being undertaken to produce new and better varieties. Increased production of other food sources, including fish culture, small animals and various indigenous plants, can augment in non-competing ways whatever nutrients are provided by staples.

Even if these alternative methods by themselves cannot achieve a doubling of world food production, they could contribute substantially to this, making up the difference that is unlikely to be produced by more modern means that are heavily dependent on inputs of energy, chemicals and water. Capitalizing on 'non-modern' opportunities will require reorientation of socioeconomic as well as biophysical thinking. It necessitates looking beyond the farm and its fields, and beyond particular crop cultivars, animal species and cultivation practices, to institutions and policies.[19]

Utilizing these Productive Opportunities

Doing 'more of the same' in either the so-called modern or traditional sectors of agriculture is not likely to be sufficient for meeting food needs in the decades ahead. Researchers, extensionists and policy makers who wish to assist households around the world to become more food-secure, healthy and well-off need to consider how to make broadly based improvements in output through evolving systems that are more intensive and more complex. These will resemble but improve upon present practices that are not fully or sustainably utilizing soil, biological and other resources.

Traditional farmers are for the most part quite resource-constrained. The technologies offered by extension services were usually developed for larger, simpler production systems that are not appropriate for the kinds of systems that the majority of farmers in the world are managing. There are wide variations in productivity within and across farming communities, with some producers tapping production potentials better than others. We look towards 'hybrid' strategies to raise production, combining the best of farmers' current practices with insights derivable from modern science to tap the power of plant and animal germplasm nurtured under optimal conditions.

There is no reason to believe that the elements of 'modern' agriculture are wrong, but neither is there a warrant to consider them (yet) complete. They offer many advantages of productivity and profit for large numbers of agricultural producers – but not for all of them, and maybe not even for a majority of farming households around the world today. Our analysis here calls into question the presumption, whether it is argued or assumed, that mainstream approaches are the best or the only way to advance agriculture in the future. For the sake of productivity and sustainability, it will be advisable to 'backcross' some of the modern varieties of agriculture, which are most suitable for advantaged producers and regions, with often more traditional methods so as to develop a more robust 'hybrid' agriculture, one that can better meet the world's needs for food, health, employment and security in this century.

Notes

1 This is not a statement in opposition to research on genetic modification, a controversial subject these days. Transgenic research has some potentially valuable, legitimate and safe uses and we would not want to see it curtailed – though more oversight and regulation and a different international property rights regime would make this enterprise more defensible and beneficial. Improvements in pest- and drought-resistance, for example, if achieved through advanced technology, could be great benefits, particularly for the poor. Our focus on opportunities to raise production through different, more intensive management practices aims at a diversified strategy of agricultural development, one which will include work on genetic improvements.

2 'Had the cereal yields of 1961 still prevailed in 1992, China would have needed to increase its cultivated cereal area more than three-fold and India about two-fold, to equal their 1992 harvests' (Borlaug and Dowswell, 1994).

3 One of the pre-eminent agricultural development projects in the 1960s and 1970s, Plan Puebla in Mexico, was set up to benefit rural smallholder households by increasing their production of maize under rainfed conditions. Maize was considered their main crop. Yet a survey in the Puebla area showed that animal production provided 28 per cent of households' income, more than the 21 per cent that came from maize and almost as much as from the sale of all crops, 30 per cent. In addition, 40 per cent of household income came from off-farm employment (Diaz Cisneros et al, 1997, p123). The project made little progress with small farmers until it sought to improve production of beans along with maize, as these crops, when grown together, produced more than maize grown by itself and also contributed more to family nutrition. Farmers' cooperation also increased when other lines of production were assisted by the project. A more recent survey of 206 households selected randomly in four villages in the northern Philippines found that livestock contributed almost as much to household incomes (90 per cent as much) as did their rice production (Lund and Fafchamps, 1997).

4 In a watershed development programme in the Indian state of Rajasthan, where a participatory approach to technology development was taken that aimed to capitalize on local knowledge, fodder production on rainfed common lands was increased eight- to ten-fold with corresponding improvements in soil conservation (Krishna, 1997, pp261–262). While such areas usually face serious physical constraints on increased production because they have been so neglected by researchers and extension personnel, they often offer substantial opportunities, previously ignored, for raising output.

5 This is discussed by Chambers (1997, especially p47). While rice, wheat and maize have received the lion's share of research funding, at least four of the international agricultural research centres in the CGIAR system have some of these other staple crops as a central part of their mandates. There are also centres now working on animals, agroforestry and aquaculture, though the centre on horticulture has yet to become part of the system (for political reasons). The centres responsible for working on rice (International Rice Research Institute – IRRI) and wheat and maize (International Centre for the Improvement of Wheat and Maize – CIMMYT) are increasingly undertaking research that relates these staples to the growing of other crops.

6 As with most generalizations, this has some exceptions. Some perennial crops make heavy demands on soil nutrients, and others such as pineapples can require heavy agrochemical applications. On the general value of perennials in cropping systems, see Piper (1994) and Piper and Kulakow (1994).

7 Managed fallows have been largely ignored in the existing agricultural literature. To remedy this lack, a South-East Asian regional workshop on intensification of farming systems was held in Bogor, Indonesia, in June 1997, with over 80 papers prepared for this collaborative effort of ICRAF, CIIFAD, the International Development Research Centre of Canada and the Ford Foundation. Documentation of these resource management systems, mostly developed by farmers, is published in Cairns (2000).

8 The German and Dutch words for agriculture, Landbau and Landbouw, are more congenial to a three-dimensional conception of agriculture as they mean land-building.

9 'Mechanization' as used here refers to tractorization. Other forms of mechanization such as water pumps can be very valuable for increasing production, but they are not necessarily linked to monocropping in the way that tractorization is.

10 Those who can afford tractors usually own the best-quality land, making their practice of agriculture appear better.

11 When the labour power available for agricultural production is a constraint in some countries, this often reflects the fact that the low prices paid for agricultural commodities are keeping rural wage rates correspondingly low, influenced by urban-biased national policies and/or agricultural production subsidies in industrialized countries. National policies in developing countries have generally favoured urban consumers over rural producers, leading to low prices for food. Low food prices also reflect the extent of poverty, which depresses the purchasing power of the poor who have need for more food but do not have the means (effective demand) with which to acquire it. In such situations, low wages and low labour productivity for agriculture do not reflect either a true equilibrium or an efficient use of resources in terms of meeting human needs.

12 See Steiner (1982). That monocrop yields, being single, are easier to measure has contributed to the popularity of monocropping as a subject for agricultural research and extension. More effort is required to assess polycropping precisely. In the 1980s a world census of agriculture by the UN FAO specifically ignored all crop mixtures, deciding to record crops only as monocultures (Chambers, 1997, p95).

13 This has been seen and documented most dramatically in Indonesia, where an IPM programme started with FAO assistance showed that rice yields would not decline, and in some instances increased, when use of chemicals was drastically cut back (more than 50 per cent), and in some cases terminated where cultural practices were changed. The key was giving farmers effective hands-on training in agroecosystem management, so that they began to diagnose problems themselves and experiment with solutions, developing alternatives to chemical dependence (Oka, 1997). Widespread use of chemicals had increased the problem of pest attacks on rice, inducing build-up of pesticide resistance in pest populations at the same time that it reduced the population of spiders and other 'beneficials' that prey on pests.

14 Recent research on rice IPM has found that maintaining the populations of 'neutral' insects in rice paddies, insects that are neither pests nor beneficials, is important. Their presence can sustain the populations of beneficials when pests have been eliminated, keeping these populations vigorous

and available to deal with any new increases in pest populations. Keeping sufficient organic matter in the soil to support populations of neutrals is becoming part of an IPM strategy (personal communication, Peter Kenmore, during Bellagio conference).

15 See Fernandes et al (1997). On infertile acid soils, farmers often need to use certain chemical nutrients such as phosphorus and calcium to prime biological processes such as nutrient recycling and nitrogen fixation. Research in Costa Rica found that when cultivating beans, mulches of organic matter prevent phosphorous fertilizer from becoming bound to aluminium and other ions in the acid soil, making it more available for plant nutrition. Phosphorus applied in conjunction with organic material produced as good or better yields as when three times as much phosphorus was applied directly to the soil (Schlather, 1998).

16 There is research indicating that the application of inorganic nitrogen fertilizer suppresses potentials for biological nitrogen fixation by reducing micro-organisms' production of the enzyme nitrogenase which enables soil microbes to transform nitrogen from the atmosphere into forms usable by the roots (Van Berkum and Sloger, 1983). This suggests that naturally occurring nitrogen can be made unavailable by the application of nitrogen fertilizers, but it does not negate the point that organic and inorganic sources of nutrients are best managed in a complementary manner. It is worth contemplating the fact that since 1950, applications of nitrogen fertilizer have increased about 20-fold (Smil, 2000, p109), while crop yields have gone up at most three-fold. While nitrogen is often a limiting factor for plant growth, if it were of overwhelming importance for plant production, we should see more proportional increases in yield, rather than such sharply diminishing returns.

17 'The importance of water-control techniques in contrast with irrigation is consistently underestimated in the literature. There is a wide range of these techniques, including those that just hold water in the sandier soils [by increasing soil organic matter] as well as a series of measures to reduce runoff where crusting is the problem. These are not just indigenous techniques. The most important ones in the next decade have large potential yield effects (when combined with inorganic fertilizers) and need to be undertaken during the crop season, generally with animal traction, and not just as emergency measures on the most degraded or most easily degraded regions (hillsides)' (Sanders, 1997, p19). On this point generally, see FAO (1994).

18 In the rice–wheat rotation systems widely used in the Indo-Gangetic Plains of South Asia, certain kinds of ploughing techniques, adjusted by depth and timing, can retain enough water from the rice season for the following wheat season, so that the amount of water needed for the latter crop is reduced (personal communication, Craig Meisner, CIMMYT/CIIFAD). Seeding wheat in the standing rice crop towards the end of its growing season enables the wheat crop to benefit from residual soil moisture, reducing the need for irrigation (personal communication, Peter Hobbs, CIMMYT). These low-till methods are being promoted by CIMMYT and IRRI because they can save water, raise yields, lower production costs, reduce weeds and herbicide use, plus reduce greenhouse gas emissions ('New Movement Among Farmers to Give Up the Plow Takes Root', press release from Future Harvest, The Hague, 2 October 2001, http://futureharvest.org/new/lowtill.shtml).

19 Most of the ideas in this chapter have been prompted from the co-authors' interactions with colleagues at Cornell University and in developing countries where CIIFAD has been engaged in collaborative, interdisciplinary programmes since 1990 to further the prospects for sustainable agricultural and rural development (Uphoff, 1996a). It is hard to know where ideas come from, and to give full or proportional credit where it is due. We take responsibility for presenting these ideas for critical consideration by researchers and practitioners, not claiming personal credit for all of them, and acknowledging our indebtedness to colleagues at Cornell and elsewhere for the stimulation and challenge they have contributed to this thinking. Critical review by Rainer Assé and Christopher Barrett of the whole manuscript was particularly helpful.

Integrated Farming Systems at Different Scales

Li Wenhua

Major types of integrated farming systems (IFS) have various structures and technical features. Integrated farming systems can be implemented at various scales. According to the sizes and characteristics, IFS can be classified into micro-, medium- and macro-scales. In this chapter we will present a general review of the major types of IFS as used in homestead gardens, eco-villages, eco-counties and forest shelterbelts.

Homestead Garden Ecosystems

Introduction

Homestead gardens, as a form of IFS on a micro-scale level, can be found on every continent. Apart from China, many other Asian countries, such as Indonesia, India, Sri Lanka and Bangladesh, are well known for their homestead gardens (Li Fadi, 1993; Li et al, 1994). Fernands and Nair (1986) put forward a definition based on their research on tropical agroforestry: '[A] homestead garden is an artificial diversified method of using trees, bushes, perennial crops and diversified poultry in the same courtyard in close combination. This compound unit of trees, crops and animals is usually managed by family members.'

China has a long history in the development of the homestead economy. Production from the home has become an important part of the self-sufficient rural economy and an important source of income for farmers. The farmers plant trees, crops, vegetables and raise livestock or fish in their yards mainly for their daily sustenance. In this way, farmers can make full use of natural resources, labour, techniques, funds and working time for agriculture, forestry, animal husbandry, fishery and sideline processing. Thus, house construction, agriculture and humans

Reprinted from Chapter 12 – Integrating farming systems at different scales, pp210–252, in Li Wenhua, *Agro-Ecological Farming Systems in China*, Man and the Biosphere Series Volume 26

together form an integrated holistic system with high economic, ecological and social benefits.

China has a high and increasing population but the growth rate of the family, due to implementation of family planning, is decreasing. On the other hand, the number of families has been increasing at a growth rate of about 3 per cent per year which, in comparison with the growth rate of the general population, is much higher. In rural areas, each individual family is allotted a small piece of land for the construction of a house and some homestead production activities. At present China has a total of 180 million families in the rural areas. The amount of land distributed to each family depends on the size of the family and the region. In general, it averages about 0.02ha per household.

It is interesting to note that though farms occupy a certain amount of land, decreasing the total arable land, total production has not decreased. This is due to integrated production and intensive management. Although sometimes homestead gardens appear to be a random mixture of trees, shrubs and herbs, a certain general pattern does exist. The components are very intimately mixed in horizontal and vertical strata, as well as in time. Complex interactions exist between the soil, plants and other components and their environment in the plots around the house.

General structure and components of homestead gardens

A homestead garden in China consists of a number of tree and fruit species and provides both productive and protective functions. Among these, poplar, willow, elms, *Sophora* and varieties of fruit trees like apple, pear, peach, date palms, *Ailantus* as well as vineyards, are common in temperate regions. In the subtropical region the litzhii, rangon, *Eryobotrya*, melia, orange and bamboo are the most common woody species. In the tropics the mango, palm, banana, jack fruit, papaya, tamarind and other tropical fruit trees are widely planted on homesteads. At ground level, a wide variety of vegetables, medicinal herbaceous plants and flowers are commonly cultivated in homesteads.

Most farm families raise a variety of animals, such as cows, buffaloes, bullocks, pigs, sheep, rabbits, chickens, ducks and geese. In the low-lying regions of southern China, on the marshlands of northern China and in coastal areas, aquaculture and mariculture is extensively practised on homesteads adjoining canals, paddy fields and ponds. Sometimes earthworms and eels or other marketable aquatic animals are also involved in these systems.

A typical homestead with a multitude of crops presents a multi-level canopy configuration, particularly in tropical areas. The leaf canopies of the components are arranged in such a way that they occupy different vertical layers, the highest level having foliage tolerant of strong light with high transpiration demands and the lower-level components having foliage requiring or tolerating shade and high humidity. Many cash medicinal plants are also permanent components of homestead gardens. Figure 18.1 shows a typical homestead garden ecosystem.

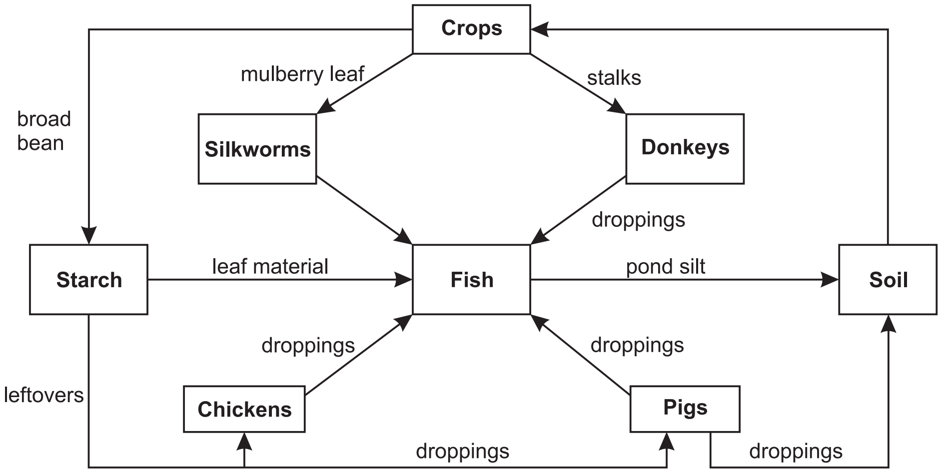

Figure 18.1 *A typical homestead garden ecosystem*

The components on the homestead are also selected according to the necessity of providing material for cottage industry and sideline handicraft production. For example, in the subtropical provinces of southern China, bamboo is planted around the family dwellings to provide material for weaving different bamboo products. The implementation of biogas production is also an important aspect in making up for the shortage of rural energy. It also strengthens the chain of nutrient cycling within the system.

Major types of homestead garden

Due to the vast area of territory and great variety of physical, economic and social conditions, different types of homestead gardens have been formulated. These can be divided into five categories, based on the components, structure and the way of management.

Cultivation–breeding

This is the most popular type of homestead garden in China. The animals include chickens, ducks, fish, hares, oxen, horses, pigs, sheep, bees, birds, earthworms, dogs, martens, scorpions and coypu. The relationship between different components may be true predators, grazers, parasitoids and parasites. But most interactions between them are through the influence of physical environmental factors.

Courtyard with dominance of woody species

With the aim of producing wood, fuel materials, fruit and attaining protection, this type is relatively simple in composition and management. The tree plantation is at the centre of the ecosystem. In fact, because of the usage of forest, there are several different forms:

- Courtyard dominated by timber tree species: In this type farmers plant trees and shrubs in and around their courtyard. The tree species differ according to local conditions and farmers' interests. In successfully afforested districts, quick growth and high yield forest are common. This type of homestead is often seen in areas with a shortage of timber and fuel in northern and north-western China.
- Courtyard with dominance of fruit trees: This is characterized by planting fruit trees around/in courtyards, mostly in the form of an orchard, but sometimes there are only a few fruit trees or even a single fruit tree in a courtyard. Species of fruit trees vary with region. For example, apricot, cherry, jujube, stone pomegranate, apple, pear, mandarin orange, tangerine, orange and grape.
- Courtyard dominated by tree seedlings and other cash tree species: in some regions, where the market is available, farmers are engaged in tree seedling cultivation. In other areas farmers are interested in cultivating cash tree crops, such as magnolia, *Eucommia* and honeysuckle, which usually create high profits.

Multi-dimensional cultivation

In order to fully use all the resources in space and in time, peasants usually design multi-dimensional homestead systems consisting of trees, crops, vegetables and edible fungi. There are several forms including:

- timber/fruit trees + melon and/or vegetables;
- lumber/fruit tree + edible mushrooms;
- trees + medicinal plants; and
- trees + flowering plants.

Cultivation–breeding–processing combination

This is developed on the basis of cultivation–breeding type in combination with some processing industries. These include handicrafts and small cottage processing industries:

1. Timber–fruit processing. This includes wood processing and craftwork such as grass weaving, bamboo weaving, furniture making and fruit processing. Farmers can gain high economic benefit if their processed products meet the needs of markets.
2. Cultivation–breeding–processing industry. This combines agriculture, animal breeding and horticulture with small agriculture processing industry in a household system. The cultivated species depend on the natural conditions of the areas. The waste from the family and the residue from agriculture harvests are used to feed domestic animals, while grains are subjected to simple processing to meet dietary requirements. The vegetables, besides being grown for consumption, can be preserved in the form of pickles and salted vegetables.

Cultivation-breeding-processing-energy integration
This is the most complex system at household level. Residents, homestead gardens, domestic animals and biogas generating facilities are well integrated into a system. It is not possible to give detailed descriptions of all the varieties and we present a case study to show how farmers manage their small homestead with full use of resources and to optimal effect.

A case study – Zhangxi's household ecosystem

Structure of the household ecosystem
Zhangxi is a farmer of Shilihe village, Sujiatun district of Shenyang City, Liaoning Province. There are three people including workers in his family, with a total area of 605m^2, of which the house area is 91m^2 and the garden area is 220m^2. In the spring of 1990, with the guidance and help of scientists, Zhangxi rearranged his household system. The optimized household ecosystem is divided into a number of basic subsystems: plastic shed, biogas digester, pig sty and toilet, garden and residents.

- A plastic shed with an area of 136.5m^2 was built in front of the house. Oyster mushrooms were planted twice within a year, first in summer (from August to the next November) and then winter (from November to the next June).
- A biogas digester with a volume of 7.5m^3 is set underground in the west of the shed, and a pig sty and toilet are constructed on the biogas digester. The human and animal faeces and urine are put into the digester automatically, to produce biogas for illumination and fuel.
- A 19.5m^2 pig pen and toilet was arranged above the biogas digester.
- The area of fields for the household is 220m^2.
- There are three persons in the family encompassing the resident subsystem.

Energy analysis and nutrient balance of the household ecosystem
The energy flow of household ecosystems is divided into three categories: energy input from outside of the ecosystem (Table 18.1), between components within the ecosystem, and the energy flow from the system to outside. Tables 18.2, 18.3, 18.4 and 18.5 describe the nutrient balances in the plastic shed subsystem, biogas digester subsystem, pigpen subsystem and garden subsystem, respectively.

Benefits analysis
It is evident that the household ecosystem is an efficient, highly productive system with considerable, comprehensive benefits. The subsystems closely interact with each other. With accumulation of productive experience and improvements in techniques, the yield of crops increased from June 1994 to May 1995. The total material was 9250kg, and 8000kg of oyster mushrooms were produced, the increase in benefit was nearly doubled. In general, the biogas pond can produce about 150m^3 of biogas used by the family and 1400kg/yr of biogas sediment which is used in the garden (roughly 150kg) and the fields outside of the household (roughly 1250kg). In

Table 18.1 *Energy flow of the household ecosystem (June 1992 to May 1995 means)*

Item	*Quantity/yr*	*MJ/yr*
I. Solar energy	448,600MJ	448,600
II. Industrial energy	18,919MJ	18,919
1 Insecticides	6kg	2183
2 Chemical fertilizer	20kg	342
3 Plastics	45kg	4712
4 Machinery and tools	0.41kg	31
5 Electric	700kwh	8393
6 Coal	1 ton	3259
III. Biomass input from outside the system	127,424MJ	127,424
1 Grain and soya bean oil	525kg	9156
2 Feed	3255kg	36,411
3 Cultural material for edible mushrooms	6683kg	80,381
4 Pigs	88kg	1477
IV. Human labour	2345h	1759
V. Biomass harvested from the system		
1 Vegetables	375kg	330
2 Grapes	250kg	230
• Consumption by residents	25kg	23
• Export to market	225kg	207
3 Oyster mushrooms	5717kg	27,394
• Consumption by residents	50kg	240
• Export to market	5668kg	27,155
4 Pork		
• Consumption by residents	45kg	759
• Export to market	780kg	13,159
5 Residue after cultivating oyster mushrooms	4484kg	19,351
• Feed	385kg	1661
• Stored compost returned to farmlands	4099kg	17,689
VI. Biogas and manure from the system		
1 Biogas	150m^3	3135
2 Animal and human manure	2150kg	38,195
3 Biogas manure	1400kg	24,878
• For gardens	150kg	2666
• For farmlands	1250kg	22,213

addition, in the homestead garden, about 10 pigs are raised twice a year and 375kg of vegetables can be provided for the whole family. About 250kg of grapes are harvested per year from the 40 grape vines planted in the garden.

Perspectives

Merits of the homestead garden ecosystem

Generally, a homestead garden ecosystem has significant economic, ecological and social benefits and farmers therefore take a positive attitude to this practice. Since

1980 many scientists and organizations have undertaken homestead garden ecosystem studies. Among the most significant is the Shijiazhuang Agricultural Modernization Institute, CAS, which made special and systematic studies and published a series of research articles. Numerous examples indicate that the land productive ratio of homestead garden ecosystems is much greater than that of general farmland. On

Table 18.5 *Analysis of nutrient balance in a garden subsystem*

Item	*Quantity/yr*	*N*	*P_2O_5*	*K_20*
Input				
Biogas residue manure (dry weight)	150.00	2.43	2.96	2.33
Biogas liquid manure (fresh weight)	200.00	2.20	0.68	2.16
Total		4.63	3.64	4.49
Output				
Vegetables (fresh weight)	375.00	1.80	1.01	1.95
Grapes (fresh weight)	250.00	1.50	0.75	1.80
Total		3.30	1.76	3.75

average, income of homestead garden ecosystems is six times that of farmland output for the same area unit. Therefore, the potential productivity of homestead garden ecosystems should not be overlooked (Yun, 1989). In summary, homestead garden ecosystems have a number of merits:

1 The multitude of crop species and animals on homesteads helps to satisfy the needs of farmers on subsistence economy.
2 The mixed feature of home gardens leads to substantial improvements in the physical and biological characteristics of the soil and environment.
3 The immediacy of human involvement and the full utilization of human waste can reduce pollution of the environment.
4 The convenient location of home gardens provides the possibility to effectively utilize family labour. Much work can be accomplished during time free of field work. The old men and women can also participate without wasting time obtaining garden plots.
5 The ratio between input and output is higher than that of conventional work in the field.
6 A special microclimate is created within homestead garden ecosystems.

Existing problems of homestead gardens

However, there are some constraints to homestead garden ecosystems. At present, the following problems shouild be seriously considered:

- Some villages and small towns lack suitable development programmes for homestead gardens. Most villages have narrow streets, small lanes, polluted water, barnyard manure in the street, threshing grounds and processing factories.
- Private houses and courtyards lack satisfactory design criteria. Not all farmers have the knowledge to organize the different components in a proper manner. This leads to a reduction in yields of individual understorey crops. Many farmers do not plant and breed suitable species, based on the space available and the food chain.

- The structure of homestead gardens is usually simple and the management level is very poor. Many profitable plant and animal species have not been introduced into the system and many advanced techniques have not been adopted. Therefore, the trees grow poorly, fruit trees and animal outputs are low, and biogas production is inefficient.
- Environmental quality of rural areas is subject to inadequate homestead garden ecosystem management. In the ecosystem, oxen, pigs, chickens, ducks, dogs, cats and humans live together in a small courtyard. Some common diseases may possibly spread. In the humid tropical and subtropical areas, a high plant density on homesteads can cause fungal diseases, especially during the rainy seasons. Sometimes, faulty utilization of wastes causes pollution.

Eco-village

Introduction

As the concept of sustainable development has spread across the world since the 1980s, a vehement campaign for Ecological Demonstrative Rebuilding for Sustainable Settlements (EDRSS) has taken place in China and many projects for ecopolis, eco-county, eco-village, as well as eco-householders were initiated and carried out across the country. The EDRSS projects were aimed at implementing the principles of IFS to the practice of local development and to explore further specific operational approaches to achieve sustainable development at different levels. Recently, great progress on EDRSS projects has been made, and eco-villages are conspicuously emerging as fruitful examples, displaying some valuable experience in human ecological rebuilding.

Main types

The eco-village is a special kind of ecological engineering, in which primary production, secondary production and cottage processing industries are integrated into a self-regulating sustainable system at the village/township or agriculture/breeding farm level. Different combinations and structures have been developed in accordance with different physio-geographical and social conditions. In China, there are many successful examples of eco-village construction. A number of projects have received awards for 'Best Eco-village' at national and international levels. In general, according to the combination of different sectors, we can classify them into six models:

1 Combination of agriculture and cottage industry. Liumingying eco-village is a good example of this and will be described later in the case studies.

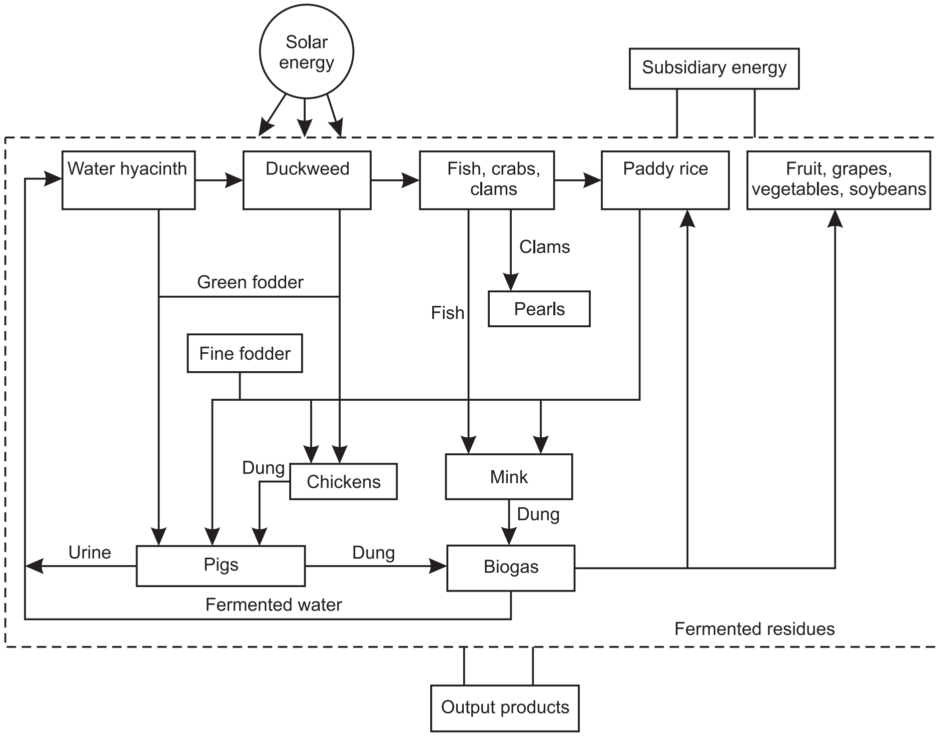

Figure 18.2 *The scheme of Xi'an eco-farming*

2 Combination of animal breeding and aquaculture. Figure 18.2 shows the Xi'an Breeding farm of Dawa County, Liaoning Province, a typical example of combining animal breeding with aquaculture and forage production.
3 Combination of agriculture, animal husbandry and cottage industry. The Xishan village in Zhibo City of Shandong Province has created a successful model combining agriculture with animal husbandry and cottage processing industry.
4 Combination of agriculture and forestry.
5 In southern China, combinations of aquaculture, animal husbandry and agriculture are very popular.
6 Integrated development model in degraded ecosystems. In degraded areas, eco-restoration, eco-reconstruction and eco-development are very important. Hongzhuang village of Huaibei City, Anhui Province, has created a special kind of sustainable agricultural development model near a coal mine.

Having recognized that it is impossible to give a detailed introduction to all of the different kinds of eco-village models, we will only take Shandu and Liumingying eco-villages as examples to show how the eco-village in China is organized and functions.

Case study I: Shandu eco-village

Background

In Jiande City of Zhejiang Province, an ecological demonstrative project, The building of Grand Shandu Eco-village System was launched in 1988, and has made remarkable achievements in the course of pursuing village-level eco-construction.

Grand Shandu Eco-village System (GSES) is located at the confluence of the Xin'an, Lan and Fuchun Rivers, consisting of four small villages. In 1988, when the demonstration project of GSES was initiated, there were 888 households with a total population of 3211. The total area of the project was 1225.54ha, of which arable land, hilly land and waterbodies were 1557, 7384 and 137.47ha, respectively [*sic*]. Gross agricultural revenue was only 2.78 million *yuan* RMB and annual income was 602 *yuan* RMB per peasant. There were only a few small cottage factories, such as an umbrella manufactory, a tea processing factory and an electroplating factory. The total output value of the village industry amounted to 11.50 million *yuan* RMB. Before implementation of the project, the main constraints to development of these villages were:

1 Low-efficiency in exploiting natural resources. The forest coverage was relatively low with barren land and mountains of 146.67ha. A large waterbody was not completely exploited.
2 Irrational structure of different sectors in agriculture. In 1988, the total agricultural output value was 2.88 million *yuan* RMB, in which cereal crops, forestry, husbandry, sidelines and fishery occupied 21.88 per cent, 58.23 per cent, 11.61 per cent, 2.35 per cent and 5.93 per cent, respectively. The latter three were relatively underdeveloped.
3 Reduction of soil fertility and topsoil depth. Because of long-term over-cultivation and high input of chemical fertilizers (the average fertilization was 3157.5kg/ha), arable land with a depth of topsoil below 13cm occupied more than 50 per cent of the total area of arable land. Fifty per cent of the land had low organic matter content (below 1.5 per cent) and all arable land had a low content of phosphorus and potassium.
4 Inefficient utilization and protection of water resources. The total water area used for fishery was only 6.93 ha, a mere 5 per cent of the total, and some parts were ecologically damaged due to over-fishing.
5 Backward village infrastructure and irrational land-use layout. Scattered houses, narrow roads and poor sanitary conditions were some typical features due to the lack of general village planning and insufficient investment.
6 Large amount of pollution emissions from rural industry. The mediocre and outmoded technical equipment used in village enterprises caused heavy pollution and environmental degradation.

The construction of GSES

In 1988, in order to promote sustainable development at the village level, the GSES project was launched. A comprehensive plan was made and a series of measures were adopted.

1. Planning and design

Based on the overall survey and assessment, and according to principles of IFS, a comprehensive four-year plan for GSES development was prepared. This aimed at promoting sustainable development with consideration for the relationship among population, resources, environment and economic development. The targets and the main contents of the plan included:

- Economic aspects. Readjusting the proportion of agriculture and industry and making industrial output value 74 per cent of the gross output value of industry and agriculture, and doubling annual per capita income.
- Environment and resources aspects. Ameliorating soil deterioration with the goal of increasing organic matter in topsoil to 2.5–3.0 per cent, developing biogas and other new energy resources, integrating agricultural by-products and organic wastes; cutting down the amount of pesticide usage, and disseminating the integrated techniques for disaster and pest control.
- Enhancing treatment capacity of 'three wastes' (gases, water and solids) from rural industry and making the emission amount within the limitation of the State's Second-class Standard, and reforesting barren hilly lands so as to raise forest coverage to 60 per cent.
- Social and cultural aspects. Setting up a hospital and sanitorium department, building a primary school, constructing a house for the aged, improving the original kindergarten, strengthening construction capacities by professional training and other educational activities, and reducing population growth rate to less than 1 per cent.
- Village infrastructure. Constructing two highways and building 500 dwelling houses.

2. Major measures

In order to realize the goals mentioned above, seven major measures were taken:

1. Readjusting the agricultural structure and promoting the overall development of ecoagriculture. The structure of agriculture of GSES was modified from the two-component-dominated pattern (agriculture + forestry) to a five-component balanced pattern (agriculture + forestry + animal husbandry + sidelines + fishery). Within the composition of agricultural output value, the contributing rate of forestry and animal husbandry was adjusted upward, while crop planting was adjusted downward and sidelines and fishery were slightly reduced. As a result, the total output value has grown drastically (Table 18.6). In the process of the readjustment of agricultural land use, the cultivated area of cereal

Table 18.7 *The output from different sectors of agriculture*

Year	*Total yield of grain (tons)*	*Yield of fruits (tons)*		*Chickens*	*Eggs (tons)*	*Honey (tons)*
		Total output	*Citrus yield*			
1988	1708	1559.3	1525	16,790	38.4	32.7
1991	1899	5402.5	5390	38,475	115.1	36
RGR (%)	111.18	246.47	153.44	129.15	199.74	100.09

Notes: RGR: Relative growth rate to 1988.

crops was kept between 120 and 126.67ha, and the production of fruits was enhanced by extending the area and increasing per unit area yield. In addition, 55,000 citrus trees were planted along the river banks, roadsides and field ridges. In the meanwhile, aquaculture has been greatly developed by using by-products of crops to process fodder. From 1988 to 1991, the yield of farm products rose, and remarkable economic benefits have been achieved (Table 18.7).

2 Developing IFS based on ecological principles. Large areas of waterbodies were effectively protected and reasonably exploited. The protection of water resources was a first priority. Advanced aquaculture techniques were introduced to increase yields. Chicken-raising and fishery cultivation were deliberately arranged according to energy flow and food chain principles. The fertility of topsoil was further improved by increasing the input of manure and decreasing the amount of chemical fertilizer (Table 18.8). Afforestation were carried out mainly in the rolling land, which accounted for 451.33ha or 60 per cent of the hilly land of the village. From 1988 to 1991 the total area of afforestation on the rolling hilly land reached 386.67ha and forest coverage rate rose from 42.4 per cent in 1988 to 70 per cent in 1991.

3 Developing the courtyard economy and constructing eco-households. A special type of animal husbandry-dominated courtyard economy was developed in GSES. About 262,000 fruit trees were planted in the courtyards with

1991	2.63	70.64	141.72	16.81
RGR to 1988 (%)	1.94	11	4.07	0.84

3.77 million kg of fruits of different varieties harvested each year. The output value of courtyard husbandry reached 80,000 *yuan* RMB in 1991. In 1990 a biogas engineering project was installed in ecological demonstration households, using the dung of chickens, pigs and humans as raw material. A 13m^3 biogas pit was built in each household. These biogas digesters could produce 1660m^3 biogas per year, which can save 9960kg of firewood. The remaining liquid and sludge from biogas pits was returned to the fields as good quality manure to improve soil fertility or to feed fish. Until 1991, 100 ecological demonstration households were constructed, accounting for 12 per cent of the total.

4 Establishing multi-step utilization and regeneration of agricultural by-products and 'wastes'. In the village there were 33 households raising 2,164,000 chickens, and all the chickens' faeces were used to feed fish, giving an annual saving in fish fodder of 113.6kg. The second application of eco-engineering was a mulberry–silkworm–pig–crop integrated production system: (i) mulberry was cultivated to produce leaves used as forage for silkworm; (ii) the silkworm chrysalis was used for raising pigs; and (iii) the faeces of pigs was returned to the fields as fertilizer. These three integrated steps constituted a complete ecological recycling chain. In 1991 the net income from silkworm cocoons, pigs and grains reached 3.19 million *yuan* RMB, 58.91 per cent more than that of 1988. A third type of eco-engineering was a chicken–pig–mushroom–biogas integrated production system.

5 Reorienting village enterprises toward environmentally healthy development. Following regulations for environmental protection, some lower-pollution or non-pollution enterprises were encouraged. Meanwhile, some strict measures were taken in heavy-pollution enterprises in order to control emissions. By 1991 the wastewater emitted from heavy-pollution enterprises such as the Shandu Electroplating Factory and the umbrella manufactory had met the State's Second-class Standard of environmental control (Table 18.9). After four years, significant environmental benefits had been attained. Table 18.10 shows the improvement in the quality of water through specific treatment, and Table 18.11 shows improvement in quality of soil. The treated rate of the 'three wastes' from village enterprises rapidly approached zero by 1991.

6 Improving village infrastructures and life quality. According to the general development plan of 1988–1991, a number of new projects for strengthening

infrastructure were implemented. As per this plan, 524 dwelling houses were built with per capita living space of 72m². Investment was provided to expand teaching facilities and improve living conditions of the village's teachers. The total area of buildings for middle schools was expanded by 1500m², a primary school was set up with an area of 300m². The highways in GSES were expanded by 5000m.

7 Promoting capacity building. A series of eco-educational activities were conducted through broadcasting, a blackboard newspaper and meetings. In addition, the authorities of the villages organized a series of training courses to disseminate useful techniques and knowledge to improve working skills of the farmers.

Benefits and experiences

The four-year practice of the GSES project achieved remarkable economic, social and ecological benefits. The total output value of industry and agriculture reached 26.34 million *yuan* RMB in 1991, or 83.07 per cent more as compared with that in 1988. The gross profit of the village economy amounted to 7.31 million *yuan* RMB, or 163.49 per cent as compared to that in 1988, and per capita income reached 1621 *yuan* RMB. increasing 169.27 per cent as compared to that of 1988. The social development of the village had ended its vicious circle and transferred from poverty to economic prosperity and ecological sustainability. The main experiences of GSES construction can be summarized as follows:

1 implementation of IFS in environmental protection and comprehensive utilization of resources;
2 overall planning and design for the integrated village development;
3 establishment of corresponding institutions to manage the relationship between humans and the environment; and
4 development of local culture and capacity building toward sustainable development.

In summary, GSES presents a successful example for sustainable development at the village level in China. Perhaps some of the experiences could also be useful for other countries, especially the developing countries, for finding their own methods in eco-village construction.

Case study II: Liuminying eco-village

Background

Liuminying Village is situated in Daxing County, about 50km from Beijing. It has a total area of 14.7ha, of which 11.6ha is arable land. The population totals 898, including 560 workers. Liumingying used to be an area of saline–alkaline soils with acute shortage of fertilizer, fuel and forage. Peasants could not earn enough to support their families and had to depend on government help. Before implementation of the programme of IFS, production was mainly concentrated in agriculture and more than 95 per cent of workers were engaged in crop production. The gross production of the village was 680,000 *yuan*, of which 78 per cent was from agriculture. The average per capita income was only 405 *yuan*. Due to long-term and excessive input of chemical fertilizers, accelerated degradation of soil and pollution of the environment had occurred.

The construction of Liumingying eco-village

In early 1983, the design for the eco-village was implemented, with help of scientists. An important step was to manipulate the production structure from monocultivation to multi-components and integrative production systems. The production system of the village comprises three interlinked subsystems. The first is the crop-cultivation subsystem including cereal crops, vegetables and fruit; the second is the breeding subsystem involving chicken breeding, duck breeding, pigs, milk cow breeding and aquaculture; and the third is the industry-sideline production subsystem, including a number of cottage industries for processing agricultural products, such as a flour processing factory, a fodder processing factory, a soft-drink production factory, a slaughter and meat processing factory and a sweet porridge factory.

In order to solve the problems of shortage of firewood and link different compartments of the production system into an integrated system, one of the successful experiments was the development of biogas. The biogas system consisted of four components:

1 Straw of grain crops, residues of vegetables and by-products from food processing were used to feed cows and pigs.
2 The faeces and urine from cows and pigs were put into biogas ponds as raw materials for biogas generation.
3 Biogas was used for cooking, water-heating and lighting.
4 Biogas residues and liquids were used as fertilizer for fishponds, vegetables or crop cultivation. Through this system, planting–animal husbandry–biogas generation–planting, or planting–agricultural product processing–animal husbandry–biogas generation–planting formed an ecological cycle with multi-energy utilization and material recycling (Figure 18.3).

In addition, in the eco-village an intensive material recycling system was also developed at the household level (Figure 18.4). A biogas generation pond was built in the homeyard, and connected to the toilet, pigsty and poultry breeding house. The excrement of animals was mixed with residues of vegetables and straws from crops

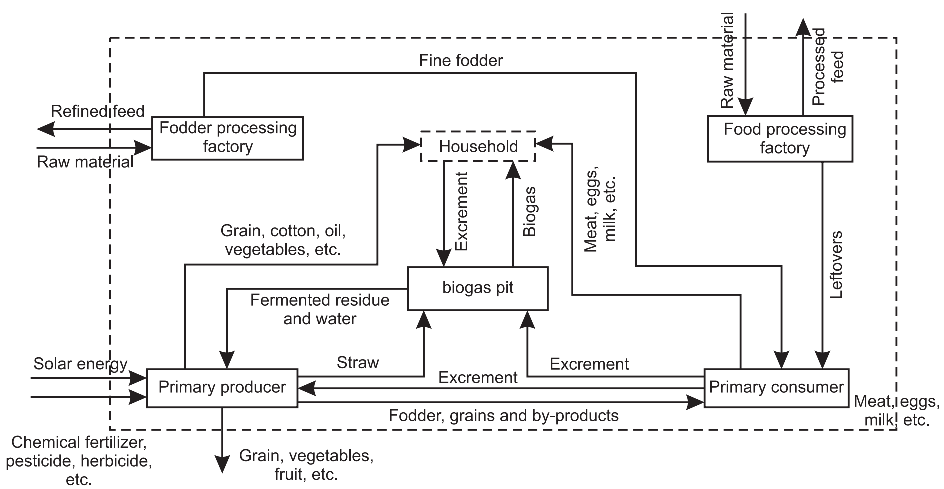

Figure 18.3 *General material flow in Liuminying eco-village (large cycle)*

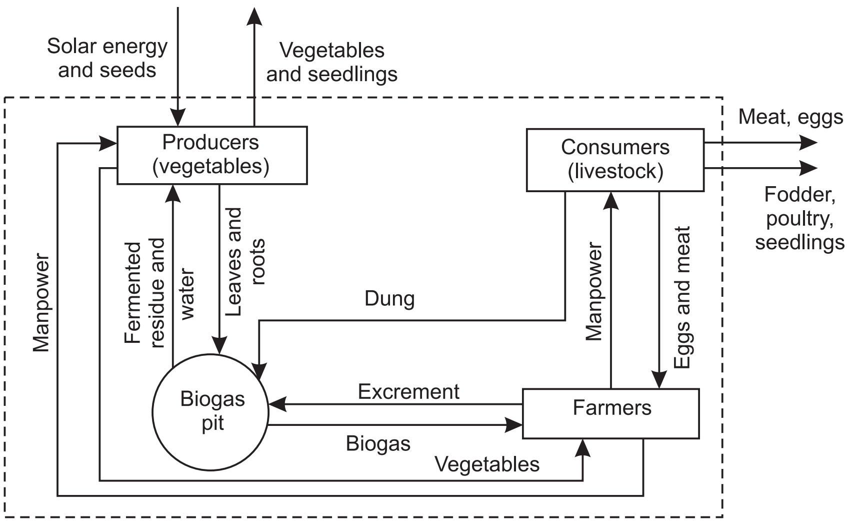

Figure 18.4 *Homestead garden ecosystem (small cycle)*

to generate biogas, which provides energy for cooking and lighting. The sludge from the biogas plant was used as fertilizer for agriculture or horticulture.

Benefits analysis

Through efforts in ecological construction, significant economic, ecological and social benefits were achieved.

Economic benefits

According to an estimate in 1993, the gross production of the village reached 100 million *yuan* RMB, of which 2.09 million *yuan* was from cultivation, 12.84 million *yuan* from animal husbandry, 400,000 *yuan* from forestry, 84.67 million *yuan* from cottage industry, of which 14.88 million *yuan* was net profit. The average gross economic growth rate of the village was as high as 57.2 per cent, and the average net profit growth rate reached 38.0 per cent (Table 18.12).

Ecological benefits

After over ten years' construction, the environmental conditions were much improved (Table 18.13). The Liumingying eco-village has been recognized by the national government as a typical model for development eco-villages in northern China and was among those awarded the World 500 best by UNEP.

Social benefits

Great progress has been achieved in social development, and this can be summarized:

Table 18.12 *Economic growth of Liuminying village*

Year	*1982*	*1985*	*1993*
Gross production (ten thousands *yuan*)	69	280	10,000
Net production (ten thousands *yuan*)	43	105	1488
Total area of fields (mu)	1900	1800	1200
Total yield of fields (10^4 kg)	89	103	120
Average yield (kg/mu)	468	572	1000
Average income per capita (*yuan*)	405	840	3703
Income per labour unit	750	1800	7206

Table 18.13 *Eco-environmental indices of Liuminying eco-village*

Year	*1982*	*1985*	*1993*
Light energy use efficiency (%)	0.55	0.70	0.90
Ratio of output to input of artificial auxiliary energy (%)	—	1.20	0.77
Ratio of organic/inorganic oxygen (%)	0.27	0.83	0.91
Ratio of nitrogen output to input (%)	0.25	0.52	0.76
Forestry coverage (%)	8.7	12.0	25.0
Ratio of economic output to its input to the total	2.66:1	1.60:1	1.18:1

1 The practices of Liuminying eco-village offer a successful model for agricultural modernization in rural areas of northern China.
2 IFS construction provides an effective approach to solve the problem of unemployment in rural areas.
3 IFS construction plays an important role not only in offering many agro-products and by-products, but also in enlivening the market economy.
4 In the process of IFS construction, a scientific and technical team were trained and awareness of sustainable development was greatly stimulated.
5 IFS construction promotes the development of a green food base and creates the environment to attract foreign investment.
6 The eco-village mitigates the differences between urban and rural areas and strengthens their interaction.

Eco-county

Introduction

In China, county is the most elementary unit in administration. It is relatively independent in policy making and administrative management. In general, a county has a land area of 1000–4000km^2 with a population of 0.2–0.8 million.

Since the 1990s, a county has been recognized as a basic unit for implementation of the strategy for sustainable development. A campaign for construction of eco-counties has been developed all over China. Eco-county construction is intended to enhance sustainable development capacity of the county by establishing ecologically sound production systems and management mechanisms through ecological engineering, ecological planning and ecological management. The construction of an eco-county requires complicated systems engineering and is multi-disciplinary. It needs the most extensive participation among decision makers, technicians and peasants and includes surveys, systems diagnosis, planning, demonstration, implementation and assessment (Figure 18.5).

In order to promote the development of construction of an eco-county, a leading group was jointly organized by the State Planning Commission, State Commission of Science and Technology, Ministry of Finance, Ministry of Water Resources, Ministry of Forestry, Ministry of Agriculture and the State Environmental Protection Agency. Based on successful experiences in different physio-geographical and economic conditions, it combines development of models with demonstration and extension. Fifty-one counties with a total area of 120,000km^2 have been chosen as pilot sites for eco-county construction (Figure 18.6). In addition, there are many other demonstration and experimental sites constructed by other ministries or various local governments throughout China. Although eco-county construction is in the preliminary stage, it plays an important role in realizing the goal of sustainable development, especially in rural agriculture. For example, Baiquan County in Helongjiang Province is one of the best eco-counties.

Case study I: Eco-county construction in Yucheng

Background

Yucheng is located in the north-eastern part of Shandong Province, with an area of 990km^2 and 800,000 *mu* of arable land. It includes 18 townships with a population of 489,000. Yucheng lies in the warm temperate zone and the low-lying land along the ancient dykes of the Yellow River. The area is characterized by frequent drought in spring; water logging in autumn, followed by serious salinization of the soils. Agriculture production is low. According to statistical data from 1986–1988, the mean annual yields of grain, cotton and edible oil were 239.5, 38.4 and 56kg/*mu*, respectively, with per capita annual income of 187.6 *yuan* RMB.

In recent years, based on the principles of IFS, a massive campaign for construction of eco-counties for sustainable development has been conducted. On the basis of the development of the county as an integrated unit, a series of measures have been taken and remarkable progress has been achieved. According to the local natural and social conditions of the area, special attention has been paid to regulate agricultural structure, diversify agricultural products, make comprehensive use of natural resources, and ameliorate land conditions. A set of comprehensive techniques has been set up to deal with problems related to soil amelioration, water conservation and improvement of agricultural production.

Figure 18.5 *The procedure for an ecoagriculture county in China*

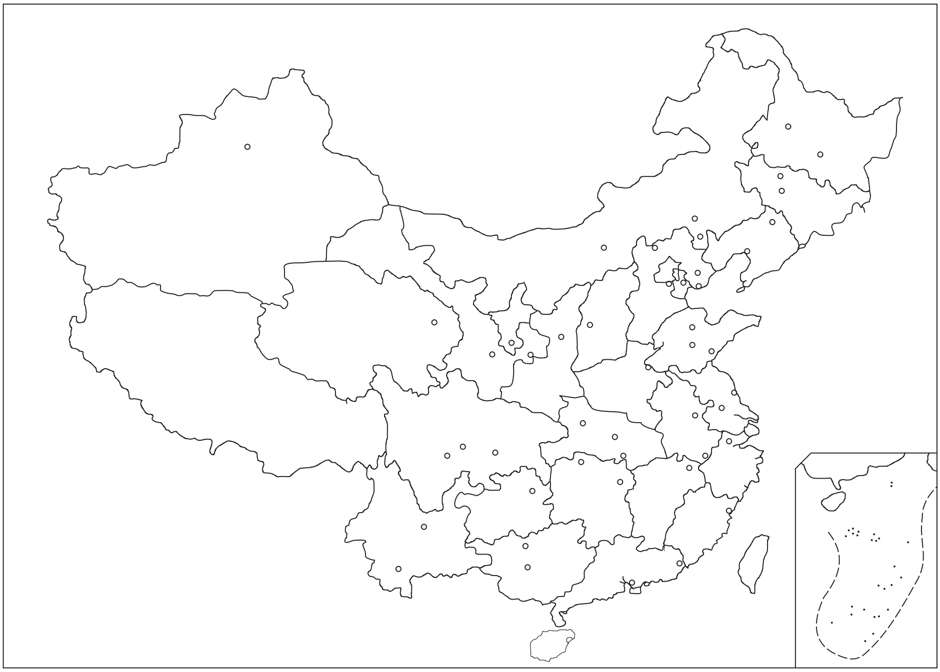

Figure 18.6 *Distribution of 51 ecoagriculture counties in China*

Major measures in construction of an eco-county

1. Regulation of agricultural structure

An important step for regulation of agricultural structure is to diversify agricultural production. Traditionally, Yucheng was a pure cereal crop area with a few animal husbandry practices. The straw of food crops was used as fuel or burned without utilization. Combining cereal farming with animal husbandry is a key measure for the regulation of the production structure. Cattle are the main domestic animals in the agricultural system. The approach for development of animal husbandry can be briefly summarized as 'Breeding by a single household, fattening by co-operative farms, and providing a service to society'. Currently, more than 90 households have cattle as a part of their agricultural management system. There are 45 accelerated fattening farms for cattle belonging to individual families. In every township a cattle breeding association has been established. A beef breeding cattle farm has been set up in the county. A beef processing factory with capacity of 50,000 butchered cattle was built in 1995. The number of big domestic animals has reached 350,000, or an average of 3.5 per farmer's family.

Along with the development of animal husbandry, silage techniques for wheat straw and green corn stems have been popularized as feed, which is good to eat, more digestible and more nutritious for cattle. The coarse protein content of fresh corn stems, which are rich in vitamins and minerals, is 1.6 per cent, 1.5 times more than that of wheat straw. According to random surveys, 18.7 per cent of farm families in the pilot area have used mixed feeds for pigs and chickens, and 53.2 per cent of families have begun to use mixed feeds with straw to raise cattle and sheep. These methods have led to a rapid growth in animal production and the meat(eggs) to feed ratio.

Because of the increase in the number of domestic animals and poultry, and the application of more organic fertilizer, the condition of salt–alkaline land has been improved and the yields of grain and cotton have increased. It is estimated that there are 1.6 million tons of manure produced in Yucheng every year. The organic matter content in the surface soil has been improved from 0.98 per cent in 1990 to 1.26 per cent in 1995 and the salt content of the ploughed layer has been lowered from 0.25 per cent to below 0.2 per cent. The effects of fertilizing and de-alkalinizing is significant. From 1994 to 1996, the government of Shandong Province organized on-the-spot meetings, and in 1995 Yucheng won an award as one of the ten best example counties in breeding cattle using crop stalks.

2. Combining agriculture with cottage industry

Stimulating the food chain structure of the ecosystem, the county combines agriculture production with industry so that primary productivity can be fully used and substances can be recycled and regenerated in effective ways. The government of Yucheng has developed brief and easily understandable guidelines for development of this interactive relationship as 'Township enterprises should be based on and supported by agriculture'.

3. Strengthening the linkage between production and scientific research

Since 1996, the Chinese Academy of Sciences (CAS) and the Chinese Academy of Agricultural Sciences (CAAS) have established an experimental station with a pilot area of 11.5km^2 in the low-lying land along the dykes of the Yellow River, which is a typical area in Yucheng. Through joint efforts of experts of various disciplines from research institutes and local technicians and farmers, a series of advanced technologies have been introduced and developed. In order to comprehensively restore salt–alkaline land and improve agriculture productivity, the measures taken include:

1 An integrated irrigation system, combining wells, ditches and pipes. An open ditch system network was constructed to overcome waterlogging and alkalinization caused by five-yearly heavy floods, and three days' 166mm precipitation could be drained within a day after rainfall. A network of wells were constructed to provide irrigation and drainage; to reduce seepage and water pressure, and to increase groundwater resources and regulate the district groundwater table. Some other techniques were also set up for well irrigation engineering using pumps and pipes (underground water transporting pipes) and for irrigation (using plotted field engineering).

2 A series of irrigation measures. Water resources in this area are very scarce. It is, therefore, important to study the characteristics of salty water and techniques to

use it for irrigation to increase productivity, while preventing salinization and alkalinization in the ploughing layer (0–20cm).

3 Adjustment of patterns of cultivation. The plantation system in the plains area has changed from a one cotton crop system to wheat–cotton intercropping. High yield, high quality and disease- and salt-resistant varieties have been introduced. In the low waterlogged land a special model of platform field-ponds was developed, where high-yield crops/vegetables are planted on platform land and fish are introduced into the pond. With the help of this model, some 1,000,000 *mu* of low land, previously unproductive, has become high-yield land; while on sandy land afforestation has taken place.
4 Fertilization methods. Based on scientific research at the experimental station, a broader spectrum of fertilizers was adopted. There was an increase in the input of animal manure through development of animal husbandry. Some 3200kg of organic fertilizer, 12.8kg nitrogen and 6.2kg potassium chemical fertilizers were applied to each *mu*. Organic fertilizers, phosphorus and 20 per cent nitrogen were used as the basis. Phosphorus is no longer applied by hand but directly into the cotton ridges. During the growing period, 30 per cent nitrogen in the bud growth stage and 50 per cent in the flowering stage were added. It was estimated that the wheat–cotton intercropping system can yield 34kg of ginned cotton and 107.5kg of wheat per *mu*, or 40 per cent more as compared with monocropped cotton.

4. Combination of demonstration with dissemination

Based on successful scientific research at the experimental station, one demonstration area covering two townships with an area of 213,000 *mu* was established. The government mobilized the people in this complex engineering project, and more than 1.400 million m^3 of earth were dug in the process of construction in 175 sites. The heavy work is usually done by machines and the delicate work by hand. At the height of construction, 12,000 labourers and 60 big machines were employed at the construction sites. Funds were raised for construction from various channels, including investment from the government at different levels, collective investment by the farmers, and loans from banks. This open policy and encouraging perspectives of the region attracted more than 20 big enterprises, institutions and foreign businessmen to invest and rent lands for development, thus ensuring the successful implementation of the programme. Different patterns of IFS were developed at various scales in accordance with different physio-geographical conditions. Some of them provided immediate returns, even in the same year as construction. A consultation group comprised of a number of experts, practitioners and decision makers was organized to provide guidance for the eco-county construction. A series of carefully selected demonstration sites with specific priorities have also been established.

Case study II: Eco-county construction in Dazu

Background

Dazu County is located in the south-eastern part of Sichuan Province. It covers an area of 1390km^2, of which 6.9 per cent is mountains, 55.7 per cent is low hills and 37.4 per cent is medium hills. The population of the county is 890,000, 90 per cent live in rural areas and provide a labour force of about 404,000. The climate is subtropical monsoon, with an annual accumulation temperature (>10°) of 63–66°C, annual precipitation is 1006mm. The arable land of the county totals 680,000 *mu* with an average per capita of 0.85 *mu*. The soil is predominated by purple soil, which is relatively fertile and suitable for cultivation of different kinds of crops. However, due to a soaring population and irrational use of natural resources, the development of the county has fallen into a vicious circle.

In the early 1980s, an integrated survey for diagnosis and design of an eco-county was carried out. It was discovered that a series of disasters dominated the area: degradation of forest resources; increased soil erosion; degradation of soil fertility; worsening of local climate; shortage of rural energy; and poor economic development. Based on this situation and agroecological principles, the county government established a general framework and concrete measures for construction of an eco-county. In order to implement the development plan, the following measures were thought essential (Figure 18.7): (1) a leading group and special

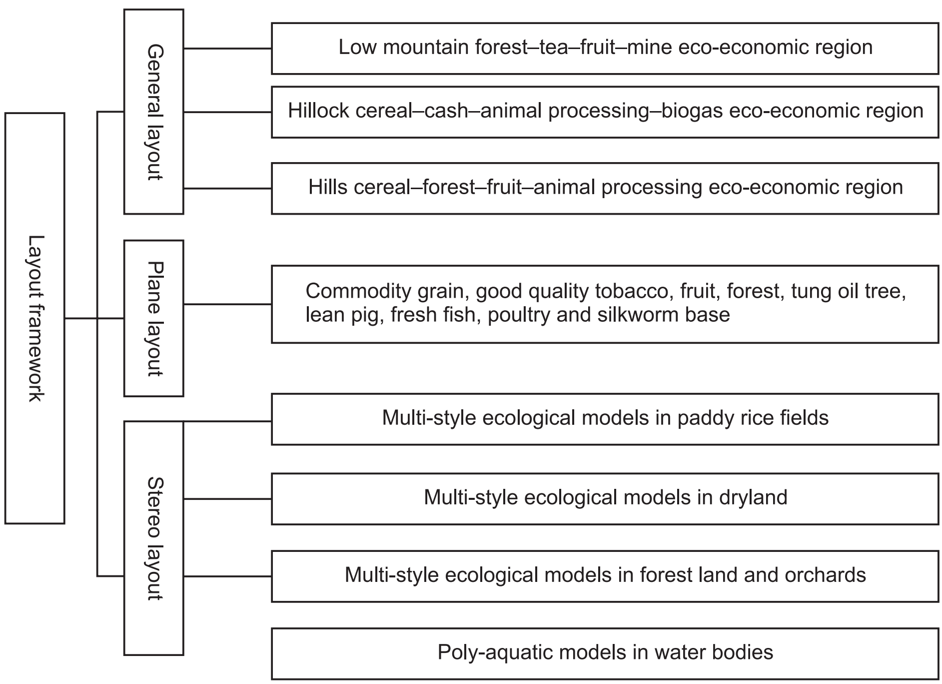

Figure 18.7 *The layout framework for Dazu ecoagriculture construction*

working office were established; (2) experimental sites were selected according to area and on the basis of scientific, technical and related decision making; (3) improving the plan and putting it into effect as a general development plan; (4) mobilizing farmers' participation and creating different ecoagricultural models suitable for prevailing conditions; (5) monitoring the development process and spreading successful experiences; and (6) signing contracts between governments, technicians and farmers.

After nine years' of construction and development in this county, forest coverage has risen, eco-environmental conditions have improved, economic growth has accelerated, and the county has become a model in ecoagricultural construction in China.

Major models of ecoagriculture

In order to use local natural resources and improve ecological and economic development, many ecoagricultural models have been created and practised: paddy rice, dryland forest, orchard, and pond/reservoir constitute the major types and there are many extensive models developed for different natural and social conditions.

1. Paddy rice–fish model

In the total area of 480,000 *mu* of cultivated fields, 160,000 *mu* have been developed in this model as: rice–mulberry–fish, rice–rice–fish, and rice–duck–fish models, occupying about 70,000, 12,000 and 1000 *mu*, respectively (Figures 18.8, 18.9 and 18.10).

2. Paddy rice-vegetables-vegetables/strawberries model

At present, this model occupies about 2000 *mu* of crop fields. It can create relatively high profits but inclusion of fresh strawberries means that it is only suitable for areas with convenient transportation and irrigation, close to markets (Figure 18.11).

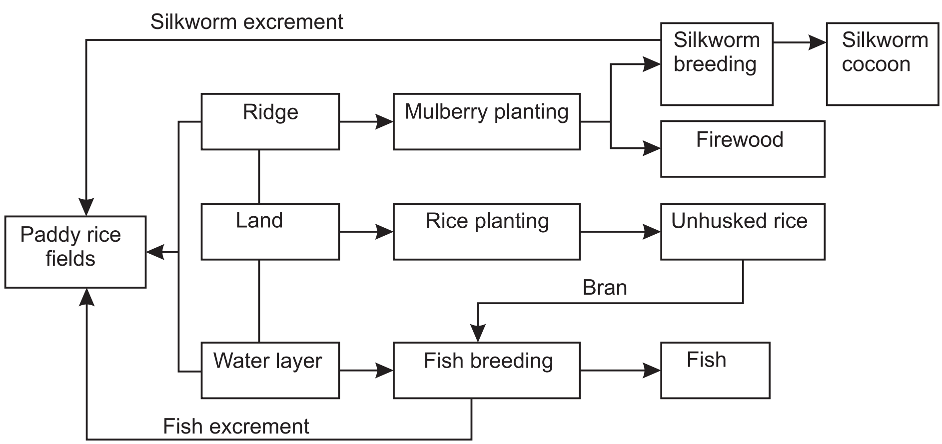

Figure 18.8 *The model for a rice–mulberry–fish ecosystem*

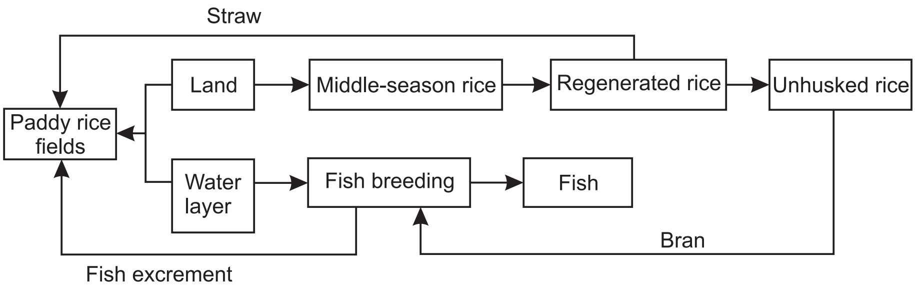

Figure 18.9 *The model for a rice–rice–fish ecosystem*

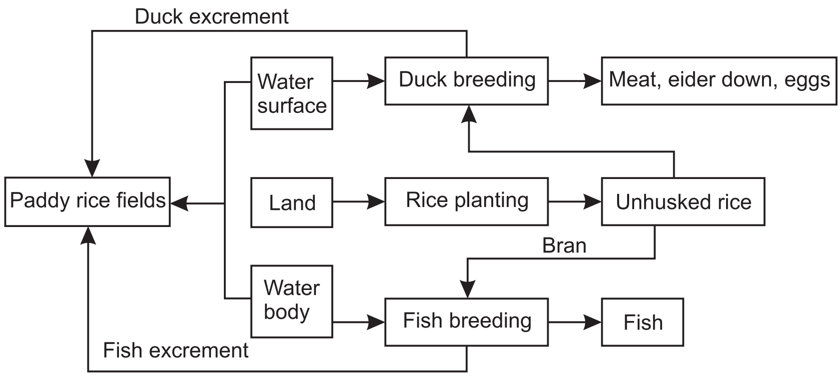

Figure 18.10 *The model for a rice–duck–fish ecosystem*

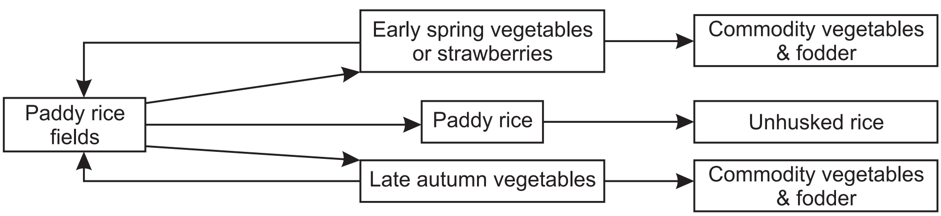

Figure 18.11 *The model for a rice–vegetable–vegetable/strawberry ecosystem*

3. Planting–breeding–biogas model

This model includes agriculture, animal husbandry and production of biogas and is a key link and the most popular throughout China, including Dazu.

Benefits analysis

In the process of ecoagriculture construction, remarkable ecological, economic and social benefits have been achieved by means of integration of economic development with environment protection, i.e. by stabilizing food production, adjusting ecological structure, protecting the environment and increasing income.

Ecological benefits

Through the construction of an ecoagriculture county, forest coverage was raised from 5.7 per cent in 1983 to 19.6 per cent in 1993 and, thus, atmospheric quality was also greatly ameliorated. Soil erosion was controlled, sources of drinking water were managed and improved, and agriculturally disastrous weather was decreased. In low mountain areas, 100,000 *mu* of bamboo entered the stage of canopy closure, 10 million plants of tung oil tree in the middle and remote mountains began to produce oil, and about 50,000 *mu* of orchard and 100 million mulberry trees are having positive effects on the environment.

Economic benefits

Through a nine-year construction period from 1984 to 1993, great progress in the agroeconomy of Dazu County has been made. The financial income was increased from 180.4 million *yuan* RMB in 1983 to 631.4 million *yuan* in 1993. Local financial input to agriculture was also enhanced from 1.59 million *yuan* in 1983 to 4.24 million *yuan* in 1993. The total income from the countryside reached 1.4 billion *yuan*, and was raised as much as 5.7 times. In 1993, the total production of food was 455 million kg, an increase of 22.7 per cent. In 1993, 3.988 million tons of fish was caught, which was 2.7 times that of 1983. As regards fruit production, this were 8.198 million kg or 2.7 times more than in 1983. The output of tung tree oil shot up to 2 million kg, 9.7 times more than in 1983.

Social benefits

Dazu was awarded the honour of Advance Unit of Agroenvironmental Protection by the Ministry of Agriculture, and was one of the approved 51 ecoagriculture counties. Many organizations and people, including many professors, specialists and students from over ten countries, showed their appreciation for these achievements. In addition, the construction of an ecoagriculture county accelerated the exploitation of natural resources and the development of sectors other than agriculture. Consciousness of environmental protection was further strengthened so that the degree of scientific decision making in agriculture was improved.

Perspectives

Based on the experiences gained in the pilot counties, the different models should be developed and implemented in accordance with various physical and economic conditions. We have summarized some of the main factors that need to be considered in further construction of eco-counties in all areas of China (Li et al, 1994).

1. Eastern coast region

This region includes the central eastern part of the Liaoning, Beijing–Tianjin–Tanggu area, eastern Shandong, Jiangsu, Zhejiang, Fujian and the delta of the Pearl River basin. These are the most developed areas in China with good conditions for development of industry and agriculture. Conservation of land resources should be the first priority in this region. High-quality, high-efficiency and high-yield agriculture should be developed here. The linkage between rural and urban ecosystems should be strengthened. The input of chemical fertilizer should be limited and rational exploitation of marshland should be made in coastal areas.

2. Songnen Plain region

Located in north-eastern China, this region includes Heilongjiang, Jilin, the northern part of Liaoning and a small part of Inner Mongolia. It is one of the most important bases of commercial grain and economic crop (e.g. soybeans, sugar beet) production as well as timber and petroleum. In the central and southern part there is little wasteland for reclamation due to a long history of cultivation. Special attention should be paid to developing agroforestry systems to strengthen the commercial base. The northern part of the region was only exploited later and there is still potential for further reclamation. The area has expanses of marshland which require special attention during eco-county construction.

3. Loess Plateau region

The most distinguishing feature in northern China is the extensive distribution of loess and loess-like deposits. Such deposits are distributed widely through Shanxi, Shaan'xi and Gansu Provinces, to form the famous Loess Plateau. The most concentrated loess region is in the middle reaches of the Huanghe River. Lack of rain, high temperatures, low humidity and dry winds during the crop growing period greatly affect crop yields. In addition, soil erosion is a serious problem constraining development in this region. About 1600 million tons of silt are carried downstream by the Huanghe each year, of which 90 per cent comes from the Loess Plateau. With the silt, about 30 million tons of nitrogen, phosphorus and potassium are lost. The huge amount of sediment carried downstream silts up the river courses causing flooding. The main task for eco-county construction is to take measures to control soil erosion and prevent degradation of grassland while developing production. A water-saving agriculture system should be established in the course of eco-county construction.

4. Huang-Huai-Hai plain region

This region covers the Haihe River plain in the north, the Huanghe River basin in the central part, and the Huaihe River basin in the south. It is one of the most important grain and cotton producing areas in China, with double cropping in its southern part and three crops in two years in the northern part. Inadequate drainage, a high water table, arid climate and strong evapotranspiration have caused salinization and alkalization that have impeded development in the region. The main task for eco-county construction is integrated manipulation of drought, floods, salinization and alkalization through effective utilization of water resources, rational construction of irrigation and drainage; effective use of straw and residues of crops, as well as the development of multi-layer and multi-component agroanimal husbandry systems.

5. South China red soil hills and low-mountains region

This area comprises the southern part of the subtropical zone and the lower reaches of the Changjiang River basin, Hunan, Jiangxi, Zhejiang, the northern part of Zhejiang and southern part of Hubei and Anhui Provinces. The organic matter in soil decomposes and leaches out rapidly. So, in spite of the nutrients accumulating quickly in the red earth, it contains only a small amount of organic matter with a high degree of acidity. It has weak water and fertility preservation capacity and is apt to be washed away or dried out. The main task for construction of an eco-county is to develop comprehensive models combining various sectors in order to fully use the natural resources and, at the same time, protect soil from erosion, and mitigate environmental degradation.

6. South-west China region

This region comprises the southeast of the Qinghai-Tibetan Plateau, west of the Guizhou Plateau, the Sichuan basin, almost all of Yunnan Province and the south-western part of Sichuan Province. It is influenced by the monsoon from the west and east, the weather is warm and clear in winter with heavy rainfall in summer. The main task for eco-county development is to raise the efficiency of water and land resources through the development of IFS. Special attention should be paid to introducing high-value cash crops and strengthening the linkage between agriculture and the processing industry so as to increase the value of commercial products.

7. North-western region

This consists of the Xinjiang Autonomous Region, the western part of the Inner Mongolia Autonomous Region, the Gansu Corridor, the Qilian Mountains and the Chaidamu Basin in Qinghai Province. Located in the central part of the Asian continent, this region receives little precipitation of uneven distribution. For construction of an eco-county, the first priority should be construction of irrigation systems and development of water-saving agriculture. Overall allocation and different combinations of cereal crops, afforestation and grass-planting are particularly important. Appropriate measures to fix sand dunes and control salinity should be incorporated.

8. South China tropical region

This region encircles the south of China, i.e. the southern part of Guangdong, the Guangxi plateau and the Tibetan Autonomous Region on the mainland, the island of Haina and part of Taiwan. With its high temperatures, abundant rain, and vast expanse of plains and hills, this region is an ideal environment for the development of tropical cash crops. But there are some unfavourable climatic factors for the development of such crops, including occasional low temperatures in winter, seasonal dry spells and strong winds. These can be prevented or alleviated to a certain extent by artificial measures. Protecting the environment, conserving land resource and developing IFS using a combination of agriculture, forestry, aquaculture and animal husbandry, are the goals of eco-county construction.

9. Qinghai–Tibetan Plateau region
The Qinghai–Tibetan Plateau is the highest in the world and covers the whole Tibetan Autonomous Region, most of Qinghai Province, the western part of Sichuan Province, north-western part of Yunnan Province, south-western area of Gansu Province and the southern border area of Xinjiang Autonomous Region. This region is characterized by its altitude, vastness, diversity and fragility. However, economic development is somewhat backward. The general aims for construction of an eco-county are to develop the regional economy by reforming the current crop-oriented cultivation to a three-dimensional economy by expanding the proportion of animal husbandry and forestry while strengthening nature conservation.

Construction of Shelterbelt Systems

China is a country with fragile ecosystems and suffers various and frequent disasters: north and north-western China is poor in natural resources and suffers frequent natural disasters such as floods, droughts, wind storms and soil erosion, which have caused tremendous threats and damage to agricultural production. In order to prevent and mitigate damage caused by disasters and improve agricultural production, the Chinese government has undertaken macro-scale shelterbelt construction in north-east and north-west China, the upper and middle reaches of the Yangtze River basin, the coastal zone and the plain region, together comprising the four biggest ecological engineering projects in China.

'Three North' forest protection engineering

Introduction
'Three North' includes the north-western, north and north-eastern region of China. This area is characterized by an arid or semi-arid climate. The 'Three North' region is not only abundant in natural resources but also rich in national heritage, with a long history. According to historical records, the region was once covered with dense forests, fertile grasslands and farmlands but, due to the wars of successive dynasties and other reasons, the ecological environment deteriorated year after year, causing serious sandstorms and soil erosion. Agriculture production and

animal husbandry were adversely affected and people lived in poverty due to lack of fuel, fodder, fertilizer and timber. It became known as a region with the most harsh environment with the most backward economic conditions in the country.

Forest resources and their distribution are influenced by the local environment which affect agriculture, livestock production and economic condition of the society. The Chinese Government has given priority to conservation and development of forest resources. Before 1977, the natural forest area in the 'Three North' region was only 16,947,000ha, of which scrub made up 42.6 per cent. The natural forests were distributed in hilly and mountainous areas of the south-east area of the 'Three North' region, and the medium and high mountains in the west, beyond the 400mm isohyet including the Tianshan Mountains, Aertai Mountains and Qilian Mountains. In the vast desert and semi-desert area, very little scattered natural secondary forest is present, with trees and shrubs such as *Populus euphratica*, *Haloxylon ammodendron* and *Tamarix chinesis*. The average forest cover of the three provinces was only 1.1–2.2 per cent. Serious destruction of natural resources has resulted in degradation. Drought frequency increased from an average of once in 17 years in the Qing Dynasty (1664–1800) to once every 1.5 years during the period 1950–1975.

The 'Three North' region is an important area for agricultural and livestock production in China, with rich solar energy resources. The annual accumulated day temperature, with daily temperature above 10°C amounts to 1500–4500°C. The annual frost-free period is 100–180 days. The annual average temperature gradually decreases from south to north and is between 12.1°C and –2.2°C. The north-western part of the region, covering 58 per cent of the total land, belongs to the arid climate zone, with an annual precipitation under 250mm. The south-eastern part of the region is in the semi-humid zone with an annual precipitation of 400–600mm. Between them, accounting for 10 per cent of the total land, is the semi-arid zone, with 250–400mm annual rainfall. Most of the rainfall is concentrated in summer, and only 10–15 per cent of rainfall is in spring (Table 18.14).

The construction of 'Three North' shelterbelt

In order to improve the natural environment and social conditions of people of the region and to speed up the development of agriculture, forestry and animal husbandry, the Chinese Government decided to build a protective forest system in the region seriously affected by drought, wind, snow storms and soil erosion. This came to be known as the 'Three North Protection System' and has been listed as a key project in the country's economic construction.

Guided by the theory of IFS, the 'Three North' shelterbelt system is designed to cover a vast area from 73°30' to 127°50' east and 33°20' to 49°48' north. It starts in Binxin County, Heilongjiang Province in the east to the Uzbel Pass, Xinjiang Autonomous Region in the west; and from the country's border with Russia in the north to Tianjing, the Fenhe, Weihe, the lower reaches of the Taohe River, the Burhanda and the Kunlun Mountains in the south, which includes 645 counties in 13 provinces, municipalities and autonomous regions, and covers an area of

Table 18.14 *Land distribution of 'Three North' region*

Areas	*Farmland*	*Forestland*	*Grassland*	*Others*
North-eastern China	22.9	16.5	45.4	15.2
Inner Mongolia and Xinjiang	2.5	3.2	38.4	55.9
Loess Plateau	29.9	18.5	35.7	15.9
Northern China	26.1	25.3	29.0	19.6

1,600,000km^2. Afforestation and shrub-grass cultivation will be carried out in a total area of 20,000,000ha. This programme is to be executed in three phases: first, scheduled from 1989 to 2000, incorporating 12,100,000ha of greening areas; second (2001–2010), 6,000,000ha are to be afforested; and the third (2010–2050) is expected to add another 1,900,000ha forest–grass–shrub plantation. On completion of the three phases of the programme, the forest–grass–grass cover should be 45 per cent in 2050, from 20 per cent in 1988. Farmland and pastures will be protected by shelterbelts; water run-off and soil erosion in the Loess Plateau will be brought under control; and the problem of firewood shortage will be basically solved. All these will lead to a great improvement in the economy and the standard of living of the local people.

As in most of the 'Three North' area, the shortage of water so seriously hinders tree survival and growth that the key to successful afforestation lies in meeting the desperate need for water. During the implementation of the programme, efforts were centred around fighting drought, as well as soil and water conservation. Technical designs were drawn up in the light of local conditions, e.g. planting the species best suited to the site, integration of trees, shrubs and grasses. Due attention is given to avoid monocultures which may invite plant diseases and insect pests. On the Loess Plateau, where soil erosion is extreme, preference is given to drought-resistant shrubs, conifers and broad-leaved trees such as little-leaf pea-shrub (*Caragana microphylla*), common seabuckthorn (*Hippophae rhamnoides*), wild peach (*Persica davidiana*), oriental arbor-vitae (*Biota orientalis*), Chinese pine (*Pinus tabulaeformis*) and black locust (*Robinia pseudoacacia*). In sandy, wind-blown areas, in addition to using of drought-tolerant species, an emphasis is put on shrub species most resistant to scouring sand, like sacsaoul (*Holoxylon ammodendron*), *Hedysarum scoparium*, *Hedysarum mongolicum* and *Callionum mongolicum*. In places with relatively favourable water conditions, quick-growing species of a higher quality are planted, e.g. Scots pine, poplar and narrow-leaved oleander (*Elaeagnus angustifolia*). In planting and maintenance, stress is placed on technical measures for fighting drought, from site preparation before the rainy season, water conservation and soil moisture preservation, to careful planting with strong seedlings and intensive management (Table 18.15).

Establishment of shrub plantation is possible in most of the area but is particularly suitable for arid and semi-arid lands. The success rate of shrubs is often twice or three times that of trees. Increase in forest cover through clothing the

Table 18.15 *Main species used for reafforestation in the Deng kou Experimental Bureau*

Scientific name	*Common name*	*Uses and features*
TREES		
Leguminosae		
Caragana arborescens (Lam.)	Pea tree	Indigenous
Elaeagnaceae		
Elaeagnus angustifolia (L.)	Russian olive or narrow-leaved marsh willow	Indigenous
Pinaceae		
Pinus sylvestris (L.) var. *mongolica* (Litv.)	Mongolian Scots pine	Indigenous
Pinus tabulaeformis (Carr.)	Table pine, Chinese pine, Flat topped pine	Indigenous to more southern areas of China
Salicaceae		
Populus bolleana (Lauche)	Xinjiang poplar	Used widely in S. America for shelterbelts and in hybridization, indigenous
Populus euphratica (Oliver) (syn. *Populus diversifolia*)	Diverse-leaved poplar	Indigenous, tolerant of heat and salinity with a large natural range
Populus nigra (L.) var. *thevestina* (Dode)	Grey bark poplar	Fairly drought tolerant, indigenous
Populus simonii (Carr.)	Weeping poplar	Largely ornamental but widely planted in early shelterbelts in China, indigenous
Salix matsudana (Koidz) var. *pendula* (Schneid.)	Pendulous willow	Produces fodder for livestock, indigenous
Salix matsudana (Koidz) cv. *Tortuosa* (Vilmorin)	Contorted willow	Ornamental, indigenous
Salix mongolica (Suizev)	Mongolian willow	Indigenous
Tamaricaceae		
Tamarix chinensis (Lour.)	Branchy tamarix	Deciduous, indigenous
Ulmaceae		
Ulmus pumila (L.)	Siberian elm	Indigenous
Sapindanceae		
Xanthoceras sorbifolia	Yellow-horntree	Deciduous, edible nuts and high-grade oil for cooking and machinery use, indigenous
SHRUBS and SUB-SHRUBS		
Leguminosae		
Ammopiptanthus mongolicus (S.H.Cheng)	Mongolian ammopiptanthus	Indigenous

Table 18.15 *(continued)*

Scientific name	*Common name*	*Uses and features*
Amorpha fruticosa (L.)	Shrubby false indigo	Deciduous, SE US
Astragalus adsurgens (Pall.)	Milk-vetch	Perennial, deep rooted, prostrate shrub, found on dry stony or gravel slopes and bogs, indigenous
Caragana korshinskii (Kom.)	Korshink pea shrub	Indigenous
Caragana microphylla (Lam.)	Little-leaved pea shrub	Indigenous
Halimodendron halodendron (Voss.)	Saltbush	Very salt tolerant, indigenous
Hedysarum mongolicum (Turcz.)	Mongolian sweet vetch	Suitable for aerial seeding, indigenous
Hedysarum scoparium (Fisch et May)	Slender branch sweet vetch	Suitable for aerial seeding, produces fodder for livestock, indigenous
Lespedeza bicolor (Turez)	Shrub lespedeza, bush clover	Deciduous, indigenous
Compositae		
Artemisia sphaerocephala (Krasch)	Ordos wormwood	Suitable for aerial seeding, indigenous
Artemisia sphaerocephala	Roundhead wormwood	Drought tolerant, suitable for aerial seeding, indigenous
Polygonaceae		
Atraphaxis bracteat	Saltbush	Very drought tolerant, deciduous, indigenous to nearby parts of Mongolia
Caligonum mongolicum (Turcz.)	Mongolian broom	Very drought tolerant, indigenous
Chenopodiaceae		
Haloxylon ammodendron	Saxoul (C.A. May)	Xerophytic pioneer shrub. Uses include fuel, fodder timber for building and roots for medicine
Elaeagnaceae		
Hippophae rhamnoides (L.)	Buckthorn	Deciduous, indigenous
Zygophyllaceae		
Nitraria tangutorum (Bobrov.)	Edible-fruited nitraria	Indigenous
Zygophyllum xanthoxylon (Maxim.)	Common beancaper	Edible buds, indigenous
Tamaricaceae		
Reaumuria soongarica (Maxim.)	Songory reaumuria, Songory tamarix	Indigenous

mountains will lead to great development of the entire region because it is labour-saving and less costly, and good results can be obtained in the short term. With adequate rainfall (no less than 200mm/year) and careful management, shrubs and some scattered trees provide pleasing views no more than three to five years from planting. Aerial seeding is carried out in some areas with sparse populations. Positive experiences of successful aerial seeding of shrub species has been gained in some places where annual precipitation is limited to 200mm.

The funds required for execution of the programme were raised from all possible sources. Private contributions in the form of investment of workdays on an individual or group basis were encouraged. Investment from collectives was taken from the gross revenue of various sectors of agriculture. The government also allocated funds totalling 267,000,000 *yuan* RMB over seven years. Another 9000 million *yuan* have been raised from other sources through either state or local channels. The funds from the state and collectives go mainly to planting and nursery activities. There are special plans to govern the use of the state funds which are put into key projects. Preference is given to those who have the best chance of success, and contracts are signed and payments are made by instalments, as requested. From time to time, assessment takes place when rewards and punishment are duly meted out. This approach functions well, guaranteeing proper use of funds and resources.

Accomplishments and effects

The joint efforts made by people of all nationalities have led to a total of 9,150,000ha being afforested, i.e. 831,800ha each year. In addition, 2,238,000ha of hills and mountains were also used to encourage the growth of forests and grasses, 23,000ha were air-seeded for forests, and 3 billion trees were planted in a scattered manner. In 11 years' of work remarkable ecological effects and considerable economic returns have been achieved through the development of farming, stock-raising and a diversified economy. In some areas of the region, sandstorms, water loss and soil erosion have been brought under control.

The forest shelterbelts have protected 11 million ha of farmland which were frequently hit by sandstorms and dry hot winds, and grain output has thus increased. For instance, the farmland shelterbelts built in the middle and western part have jointly formed a large system of forest networks. Obvious changes have taken place in regional microclimate. According to fixed spot observations made by the Jilin Institute of Forestry Survey and Planning, wind speed was reduced by 23.7 per cent on average; air temperature was raised by 0.63°C; soil surface temperature increased by 3°C; evaporation was reduced by an average of 15.2 per cent; soil water content increased by 18.6 per cent; and relative humidity by 12.6 per cent. About 40 per cent of the planted trees in the shelter belt networks have matured. This has alleviated the shortage of timber, fuelwood, fodder and fertilizer.

Grassland of more than 8,800,000ha has been established in desert and semi-desert areas of the region, controlling soil desertification, salinization and grassland degradation, and grass output has increased by over 20 per cent. In Maowusu and Holqin deserts forest coverage has gone up from 7 per cent and 10 per cent to 16.1 per cent and 18.8 per cent, respectively, since the project started. The ecological environment in the two areas has fundamentally improved.

In the Xishui He River valley and Weibei Plateau of Shanxi Province, forest coverage has considerably increased. Water loss and soil erosion have been brought under effective control with quite remarkable economic effect. Over 730,000ha of fuelwood forest produced three million tons of fuelwood per year which, combined with other energy resources, has solved the fuel problem for some five million households in the countryside. The area of economic forest has increased from 826,000 to 1,440,000ha which produced 2,750,000kg of dried and fresh fruits. The forest coverage of 12 cities and counties situated in the upper reaches of the Yellow River in Gansu Province increased from 8.7 per cent in 1977 to 12.3 per cent, and erosion-control area cover more than 300,000ha. In Shanxi Province three main sand-control forest belts have been established along the Great Wall, in the border area with Inner Mongolia and the foothills of the Baiyu Mountains.

Since the beginning of the project in 1978, the state and local authorities have invested 2420 million *yuan* RMB, and a total of 1050 million man-days have been spent by the people and local army units. Outstanding accomplishments have been achieved and the results are remarkable. As far as the entire project is concerned, this is just the first step of a 'long march', but it is firmly believed that this great IFS programme, which will benefit both our and future generations, can be brought to a successful completion under the leadership of the Chinese Government.

Shelterbelt systems in the middle and upper reaches of the Yangtze River Basin

Introduction

The Yangtze River (Changjiang) is the longest river in China, with the widest drainage area and the largest water flow. It originates from the Qinghai–Tibetan Plateau and flows eastward across Xizhang, Qinghai, Yunnan, Sichuan, Hubei, Hunan, Jiangxi, Anhui and Jiangsu Provinces/Autonomous Regions and Shanghai Municipality and enters the Pacific Ocean. The Yangtze River can be divided into three main parts, in accordance with physio-geographical conditions: the upper reaches (from Zhimenda of Qinghai Province to Yichang of Hubei Province), the middle reaches (from Yichang to Hukou of Hubei Province), and the lower reaches (from Hukou to the mouth at Shanghai) (Ren Mei'e et al, 1985).

The upper reaches of the Yangtze River lie on the Qinghai–Tibetan Plateau, with an elevation of 4000–5000masl. In the eastern margin of the Qinghai–Tibetan Plateau, all mountain ranges turn south-east or directly north–south, forming the famous Hengduan Mountain system with deep gorges cutting the upper reaches of the Yangtze River. The region which extends from the outer rim of the Qinghai–Tibetan Plateau, eastward to the Wushan Mountains, is mainly

Table 18.16 *The basic hydrological features in different sections of the Yangtze River*

Section	*Upper reaches*	*Middle reaches*	*Lower reaches*	*Total*
Length (km)	4529	927	844	6300
(%)	72.0	14.7	13.3	100
Drainage area (km^2)	100.55	67.74	12.56	180.85
(%)	55.6	37.6	6.8	100
Annual discharge (10^8m^3)	4543	4636	615	9794
(%)	46.4	47.3	6.3	100

composed of plateau and basins with elevations of 1000–2000m. Eastward from that line and extending to the mouth of the Yangtze River is the third great step. In the lower Yangtze River basin, the third step staircase, there are extensive plains largely below 50m. This region is famous for grain production. The Yangtze River has a vast drainage area of $1.8 \times 10^6 km^2$ and a particularly heavy annual run-off of $9.79 \times 10^{11} m^3$, accounting for 37.2 per cent of the national total. In terms of average flow, the river has a water resources reserve of 2.3×10^8kw, or 42.5 per cent that of the whole country. The average annual flow of the Yangtze River accounts for over 30,000m^3/s, or 17 times that of the Huanghe River. Table 18.16 shows the basic features of different sections of the river.

In order to relieve the Yangtze River flood problem, large-scale hydrological works have been done since 1949. Dykes along its main stream and its main tributaries have been repaired, raised or strengthened. The Jingjiang flood diversion project, the Hanjiang flood diversion project and other flood-storage projects have been built along its middle reaches, where the area is often hit by unusual floods. Many lakes have been dredged, and this has increased the capability of the Yangtze River to prevent flooding. At the same time, more than 40,000 small reservoirs for irrigation, and over 500 big and medium-sized reservoirs for multi-purpose utilization have been built. Currently, the Three Gorges Project, attracting worldwide attention, is underway, which will play an important role in preventing natural disasters and providing the electric power for economic construction and development of the Yangtze River basin.

The climate of the middle and upper reaches of the Yangtze River basins is characterized by a vertical differentiation of climatic zones (Table 18.17). However, most of the areas located between 2000–3000m belong to a subtropical zone with warm winters, cool summers and spring-like weather for all four seasons. Although climatically the region does not have marked contrasts in seasons, it does have notable differences in dry and wet weather. Generally, it is dry from November to April and wet from May to October.

The forest vegetation in different sections of the Yangtze Basin varies significantly. In the upper reaches of the Yangtze River, forest vegetation in some areas has maintained its natural structure and the latitudinal differentiation of the vegetation

Table 18.17 *Climatic conditions of the major cities along the Yangtze River*

City	*Mean annual temperature (°C)*	*Annual precipitation (mm)*
Yushu	2.9	480.5
Changdu	7.5	477.7
Huili	15.1	1130.9

Anqing	16.5	1389.2
Wuhu	16.0	1169.8
Nanjing	15.3	1031.3
Shanghai	15.7	1123.7

are distinct, though most areas have suffered human disturbances. On the humid slopes, less than 2500masl, the original forest vegetation features subtropical mixed evergreen–deciduous broadleaf forests. The dominant species are in the genera *Quercus*, *Alnus*, *Lithocarpus*, *Liquidambar*, *Populus*, *Castanopsis* and *Cyclobalanopsis*. Most of these trees are somewhat cold-resistant evergreens, mixed with some temperate deciduous broadleaf trees. The forests have a complex form with a three-layer structure. The first layer consists of deciduous broadleaf trees, while in the second and third layers are evergreen broadleaf trees. On the forest floor the bamboo, *Sinarundinaria chungii*, grows. The deciduous broadleaf trees are mainly of the beech family, which reflects the extreme humidity of the local environment. The representative species of evergreen broadleaf trees are *Cyclobalanopsis glauca* of the beech family, *Phoebe bourpei* of the laurel family, and *Schima superba* of the tea family. Between 2500m to 3000m there are mixed coniferous broad-leaved forests. From 3000m to 4000m and even higher is the sub-alpine forest belt, dominated by species of spruce and fir. Alpine scrub, meadows and nival vegetation can be found in areas higher than 4000m. In the Hengduan Mountains are valleys with less precipitation, where the so-called dry and hot valley vegetation occurs.

In the middle reaches of the Yangtze River the zonal vegetation is mixed evergreen and deciduous broad-leaved forests, growing on yellowish-brown soil. The natural forests are mainly distributed on mountains and hills. The forests are green all year round and contain an arbour layer, a shrub layer and a herbaceous layer. The trees are mainly in the genera *Cyclobalanopsis* and *Castanopsis* of the beech family and associated deciduous trees of beech, walnut and maple. Among the coniferous trees, masson pine (*Pinus massoniana*) and Chinese fir (*Cunninghamia lanceolata*) are dominant below 600–800m. Above this, Huangshan pine (*Pinus hwangshanensis*) grows. On the low mountains and hills cash tree crops such as chestnut, tung oil trees, Moso bamboo (*Phyllostachys pubescens*), Chinese sapium, tea trees, lacquer trees and citrus are cultivated. But warm-temperature fruit trees such as persimmons, Chinese chestnuts, pears, peaches and apricots can also be grown in this region. During recent decades many species have been used for afforestation. Besides the endemic species such as Chinese fir, masson pine and *Metasequoia glyptostroboides*, moso bamboo, *Quercus accutissima*, *Cinnamomum camphora*, *Castanopsis fargessi* and *Sassafras tzumu*, as well as many other fast-growing species such as *Pinus elliottii*, *Pinus taeda*, *Chamaecyperis*, spp. and *Eucalyptus* spp. have been introduced for afforestation.

In the lower reaches of the Yangtze River are vast low-lying plains. The zonal vegetation is mixed evergreen and deciduous broad-leaved forest, and the zonal soil type is yellowish-brown soil, restricted to low mountains and hills. The extensive plains have been turned into cultivated vegetation and paddy soil. Even on low mountains and hills, original mixed forests were mostly destroyed and have been substituted by secondary growth of shrubs and grasses, and partly planted with masson pine and other economically valuable tree crops, such as tea and fruit trees. The great contrast between the intensively used and densely populated plains and the rather extensively used and sparsely populated slope lands is an outstanding feature of the region.

Main environmental problems

Degradation of forest

The long history of exploitation, increasing population pressure, the demand for timber and fuelwood, inadequate forest management, illegal use of marginal land, and poor economic development of the region, have led to declining forest cover and timber stocks. For instance, in Sichuan Province, forest cover decreased from 20 per cent in the 1950s to 13 per cent in the 1980s. While forest cover in the Sichuan Basin accounts for only 4 per cent. A similar situation is found in other provinces along the river; in Jiangsu, Anhui and Guizhou Provinces forest cover is only 8 per cent, 13.5 per cent and 15.1 per cent, respectively. So, the water conservation and regulatory role of forests in the Yangtze River has decreased significantly.

Degradation of forest quality has also occurred. Many forests in the region are being degraded into low-value, secondary forest through repeated human disturbance, low soil fertility and careless management. In the upper reaches of the Yangtze River there are over 600,000ha of low-value forest, most of them in the Jialing River area and accounting for 60 per cent of the total forest. Pine and cypress are the dominant species of low-value forests (Yang Yupo, 1993). It is an arduous task to improve the current situation of low-value forests and replace them by high-yield forests with effective environmental protection.

Table 18.18 *Variation of soil and water erosion areas*

Soil erosion

Soil erosion in the Yangtze River Basin is caused by both natural and man-made causes. The natural causes in the Yangtze River watershed include fragile mountain environments, high intensity, long duration rainfall, high stream density, steep stream gradients, mass movements, debris flows and landslides. The causes induced by human activities include deforestation, inappropriate land management practices, road construction in fragile lands, improper water collection, transportation and use of water. According to statistics, the total discharge of the Yangtze River reaches 5.02×10^8 tons per year, or 19.1 per cent of the national total. At present, the water flow of every tributary in the upper reaches is decreasing, but the content of silt is increasing. For example, in Sichuan Province, the average silt content of water flowing in the Three Gorges area was about 5.1×10^8 tons in the 1970s, and increased to 6.8×10^8 tons in the late 1980s. The general status of soil erosion in different provinces of the Yangtze River Basin is given in Table 18.18.

Since 1954 natural water bodies in the middle and upper reaches of the Yangtze River have declined by some 12,000km^2. For example, the surface area of Poyang Lake has decreased by 36 per cent. In the Dongting Lake area 166,000ha have been reclaimed for farming. Some 10,000ha of land in the Taihu Lake area were also turned into polders between 1969 and 1974. In the Jianghan Plain the number of lakes with a water surface area over 50ha has dropped by 40.36 per cent from the 1950s to the 1980s and the total water surface area shrank by 43.67 per cent (The National Conditions Investigation Group under the Chinese Academy of Sciences, 1992).

Construction of protective forests in the upper and middle reaches of the Yangtze River

In 1989 the state approved the 'Overall Plan for the Construction of the Protection Forest System in the Middle and Upper Reaches of the Yangtze River'. The objectives were not only to reduce water and soil loss, but also to improve the ecological environment for agriculture and to accelerate development of the economy in mountain areas. Under the guidelines of IFS, a multipurpose and comprehensive protective forest system was designed. This system integrates protective forest with cash crops, fuel wood, timber and other forest with specific purpose species. In the general plan of afforestation, arbour trees, shrubs and grass are combined. The coniferous and broad-leaved trees, deep-rooted and shallow-rooted plants, fast-growing and slow-growing plants, supplement each other to form an integrated system with a great variety of plant species and multiple layers (Investigation and Research Team of Sichuan Forestry Society, 1990). This is a huge forestry ecological engineering project, covering 13 provinces/autonomous regions, 645 counties, and with a total area of $4{,}06 \times 10^6$km^2. The total area for afforestation is about 20×10^7ha. It is proposed that the areas of afforestation will consist of 1.21×10^7ha between 1989 and 2000; 1.90×10^6ha between 2011 and 2050. After completion of the project, the forest coverage will be raised to 45 per cent.

The Yangtze River protective forest system may be divided into six eco-economic zones: the Jingsha River watershed on the western plateau of Yunnan and Sichuan Provinces, the Hanshui River watershed in the Qingling Range–Dabashan mountainous area, the Jialing River watershed in the Sichuan Basin, the Wujiang River watershed on the West Guizhou plateau, the Yangtze Trunk River watershed in mountainous areas of Sichuan and Hubei Provinces, and water systems of Dongting Lake and Poyang Lake in hilly areas of Hunan and Jiangxi Provinces.

In the upper reaches of the rivers running across high mountains in western Sichuan Province, north-western Yunnan Province and the highlands of the northern and south-western edges of the Sichuan Basin and Qinling–Dabashan Mountains, special protective forest systems for soil and water conservation, in combination with timber production forests, should be initiated. The forest of multiple purpose use, including soil conservation, fuelwood, economic and shelterbelt forest networks, should be established in hilly areas of the Sichuan Basin. A forest system made up of timber, economic, and soil and water conservation forests should be undertaken in the mountainous areas of the Wujiang watershed. In the Dongting and Poyang Lake region and the lower reaches of the Yangtze River, bank protective and economic forest networks are the key types for protective forest construction.

The distribution and layout of different kinds of forests should be based on the concrete conditions. Taking the hilly areas of the middle and upper reaches of the Yangtze River as an example, the general layout of its protective forest system is as follows: water and soil conserving forests on the top of the hills and on the slopes, economic forest belts serving to conserve soil and protect earth banks between farmland, and farmland protection forest networks between hills and in the valleys and plains. This arrangement provides step-like forest protective networks which run from hill tops to valley lands, intercepting water and conserving soil at different levels. This provides a spatial pattern of water and soil conserving forest in hilly areas which combines protective and productive functions in the agroforestry system.

In general, gentle slopes of less than 10° gradient and valleys where soil erosion is infrequent are suitable for growing food or cash crops. Slopes of 10–20° gradient are suitable for growing economic or cash forest. Accelerated development of cash forest plantations is absolutely necessary in order to mobilize participation to overcome difficulties due to shortage of funds for long-term silvicultural programmes in mountain areas. Economic forests are a special category which are mainly used for non-wood products such as fruits, edible oils, fibres, pharmaceuticals, resins, gums, waxes and many other raw materials for industrial and commercial purposes. In the subtropical area of the lower reaches of the Yangtze River the most widespread species with economic potential are tea oil trees (*Camellia oliefera*), tung tree (*Aleurites fordii*, *A. montana*, *Sapium sebiferum*), Chinese walnut (*Juglans regia*), Chinese chestnut (*Castanea mollissima*), lacquer tree (*Rhus verniciflorum*), star anise (*Illcium verum*), eucomia (*Eucomia umoides*), and citrus fruit groves (*Citrus reticulata*), *Litchi chinenses* and *Euphorbia longgan*. Slopes of more than 20° gradient and hills need tree or scrub species to conserve water and soil. The common species of timber used for soil protection are *Pinus massoniana*, *Pinus elliottii*, *Cunninghamia lanceolata*, *Quercus accutissima*, *Eucalyptus robusta*, *Sassafras tsumu*, *Robinia pseudoacacia*, *Ailanthus altissima*, *Albizzia julibrin* and *Paulownia fortunei*. In recent years, after overall planning and comprehensive improvement, a number of red earth areas that were low yielding in the past have changed dramatically.

In the Yangtze River Basin there are about 60 tree species, 20 shrub species and more than 30 herb species (not including those existing in silviculture environments) used for protective forest construction. Most of these species are indigenous, a few exotics suitable for these areas were also introduced, based on experience and observation in small-scale plots. Community structure and stand density determine forest function. They also affect ecological and economic benefits of the protective forest. Table 18.19 shows the major tree species for reforestation and their planting density in the Yangtze River Basin.

Effects of afforestation for environmental protection and regional development

1. Improving the environment

Seven years after the implementation of the Yangtze River Protective Forest Project, the environment of the Yangtze River Basin has been improved significantly. It is estimated that 2,707,500ha of multifunctional protective forest have been reforested during the Eighth Five Year Plan period in the upper reaches of the Yangtze River (Lu, 1996). The vegetation cover of the whole Yangtze River Basin has increased over 5 per cent. The proportion of protective forest and mixed forest has increased nearly 100 per cent. Most of the reforested woodland stands have closed and grown well. Shrub and herb layers of stands have developed rapidly. As a consequence, loss of water and soil has been primarily controlled and the area of soil degradation has been greatly reduced (Yang, 1993). In Xingguo County of Jiangxi Province, for example, the area of soil erosion was reduced from 160,000ha to 50,000ha and forest cover has increased 20.8 per cent, as compared with the 1980s. This previously well-known 'desert area of the southern Yangtze River' for water

Saccharum spowtaneum		10,005–40,020		

and soil erosion has become a prosperous and green county (Li et al, 1994). Field observations from watershed management show that protective forests have good effects on water conservation, while improving soil structure and chemical properties (Tang and Guo, 1995; Xiang, 1996). In addition, the crown and understorey layer of protective forest are capable of intercepting precipitation, reducing flow speed of surface run-off, increasing soil penetrability and enhancing water and soil conserving capacity. The protective forests have played a key role in maintaining soil fertility and conserving water and soil.

2. Providing favourable conditions for rural development

On the basis of reforestation with protective forest systems and implementing the ecological benefits of these systems, a great number of forest production bases have been established. Considerable economic benefits have been gained in terms of timber, fuelwood and economic forest products, such as medicines, fruit and other non-wood products. During the National Eighth Five Year Plan, more than 600,000ha of economic forests were reforested, and some 8000 township-owned forest farms were established in the middle and upper reaches of the Yangtze River Basin. Small-scale orchards, gardens for cultivation of medicinal plants, tea gardens, mulberry woodlands and bamboo gardens are growing in the area. The forests have improved the environment and microclimate for agricultural development and have promoted development of green industry. The cash income from the forest has reached nearly one-quarter of the farmers' total income.

According to observations and research in the experimental sites distributed in different topographies it was found that, after execution of the project, the forest coverage has increased and the environment of the region has improved significantly. For example, forest coverage has increased from 17.6 per cent to 41.6 per cent in low mountain areas, from 8 per cent to 39.9 per cent in hilly areas and from 12.7 per cent to 24.7 per cent in low hilly areas. Soil erosion has dropped from 4000ton/ha to 2000ton/ha. Considerable economic benefits have also been gained in terms of timber, fuelwood and economic forest products. In Wangchanggou small watershed, Guangyuan City, 33,000 fruit trees have been grown with an expected annual fruit yield of 800,000–1,000,000 *yuan* RMB. In addition, the blend of forests and grasses in the area supplies sufficient grass to feed between 1000–2000 cattle per year. It is expected that, by the year 2000, adjusting the optimal ratio between agriculture and forestry will likely reach 0.70–0.75 : 0.25–0.30 in hilly areas, and 0.25–0.30 : 0.70–0.75 in mountainous areas. The structural ratio between protective, timber, economic and fuelwood forest will likely attain 0.40–0.50 : 0.25–0.30 : 0.20–0.25 : 0.05, respectively, in hilly areas. While in the mountainous region, the structural ratio of protection forest will reach 50–60 per cent, timber forest 30–40 per cent and economic forest 10–15 per cent.

Perspectives

Although afforestation in the Yangtze River Basin has made preliminary progress in the past several years, there are still many problems to be solved for improving its forestry.

1. Conservation and rational utilization of existing forests

The felling of existing forest must be well planned in both local and state-owned forests. The timber felled each year should not exceed the annual increase in timber volume. To take into account the long production cycle of forests, and to compensate for lost forest resources resulting from excessive cutting over a long period in the past, a fixed forest culture fee should be levied on the selling price for timber, bamboo and other forest products. Forest culture funds should be used mainly for preparing deforested land for production and for planting new forests. The forest department will conduct scientific research to increase the wood utilization rate and to discover potential uses for tree species that are currently not being used but which may have domestic or commercial potential. (Li Wenhua, 1993)

2. Afforestation and reforestation

To plant trees and afforest the country is a basic national policy. In order to fulfil the task effectively it is necessary to continue to carry out the construction of forest systems along the Yangtze River, and to establish timber production bases in the hilly regions. These areas have high precipitation, with good conditions for development of fast-growing trees in short rotation. In addition to afforestation organized by forestry organizations, a voluntary mass afforestation campaign is being encouraged. For example, according to a resolution of the People's Congress, all Chinese citizens above the age of 11, apart from the old, weak, sick and disabled, are obliged to plant three to five trees every year or provide an equivalent amount of labour by cultivating saplings, tending trees or other afforestation work as a condition of their permit. The locals have to carry out afforestation campaigns around 'four sides' (around houses, villages, roads and ditches). In addition to forest plantations, to assist natural regeneration, hillsides should be closed to facilitate reforestation and redevelopment of forest ecosystems. Aerial sowing is especially important in sparsely populated remote areas.

The department of forestry will undertake and encourage the development of agroforestry in the region in general, and in the middle and lower reaches of the Yangtze River Basin in particular, where population pressure is particularly acute and cultivated land is scarce. Research programmes should be conducted to identify the optimal planting and cropping patterns under various conditions in order to improve overall productivity and to determine ecological compatibility.

3. Rectifying the existing laws and management systems

These include: adjustment of the timber value in accordance with marketing requirements; establishment of a rational subsidy system for forest environmental protection; implementation of a low tax system for ecologically sound and environmental protection-oriented forestry management units and enterprises; establishment and improvement of a system of proper rights on exploitation; repayable use and transfer of forest resources; development of a forestry production insurance system; and accelerating multiple channel fundraising.

4. Improving nature reserve construction

A nature reserve is a legally confined area where various important ecosystems and their environment, endangered species and national historical relics are placed under protection and management. The Yangtze River Basin is characterized by its rich biodiversity, unique ecosystems and numerous endemic and endangered species. During the last decades many nature reserves have been established in this region, mostly located in forest areas. Although significant progress has been made in establishing nature reserves in the region, much work is still to be done in the future and it is important that every nature reserve should have a proper management plan and implement it *in situ*.

5. Scientific research

China will give special attention to forestry research by developing projects to solve the key problems of afforestation, and engage in research on seed multiplication, containerized saplings, vegetative propagation, high-yield tree saplings and dryland afforestation. A quota system and methods for increased forest utilization and regulation of forest reclamation will be established. China will take various measures to improve the maintenance of the ecological values of forests. It is important to establish forest inventory, monitoring and assessing systems for forestry. It is necessary to develop advanced forest utilization and exploitation techniques that minimize the impact on the environment, or have low pollution value, and work to develop and promote non-timber forest products. China will develop comprehensive prevention and control methods for pests and plant diseases, detection and prediction of forest fires, and will research and spread new fire prevention techniques.

6. Training and education

In order to mobilize the people's participation and improve forest management, an important goal will be to develop a forest public education system to make the value and multipurpose usage of forests known to the public. It is important to train forestry professionals and workers, with the emphasis placed on the young and women. China's Agenda 21 (The Editing Committee, 1994) states that China will set up demonstration project bases and training centres dedicated to the layout of shelterbelts and networks for fast-growing and high-yield forests. Model forest policies and management centres will be established and one prefecture from each province or autonomous region will be selected for setting up demonstration units. China will set up a national training centre for forest resource management and forestry administration. The afforestation engineering of the Yangtze River Basin is not only an ecological rehabilitation project, but also an economic reconstruction process. It closely relates to the long-term interests of people. Therefore, it is important to formulate a series of technical and economic policies for protective forest engineering.

7. Multi-channel fundraising

The local people have put their efforts into the afforestation campaign. However, for conducting such big engineering projects with long-term returns, fundamental funds are necessary. The people's enthusiasm should be encouraged by incentives from the government at various levels. The government has decided to increase investment in forestry from the current 0.14 per cent of GNP to 0.3–0.4 per cent by the year 2010. A multi-channel fundraising system should be encouraged.

8. International cooperation

China has signed several major conventions concerning protection of biodiversity and forest management. Cooperation will be in accordance with the mechanisms of relevant conventions and in accordance with national and local conditions, so as to share benefits and to obtain financial and technical assistance. China will continue to expand international, bilateral and multilateral cooperation, and wishes to enhance exchanges and cooperation in the fields of management, scientific research, technical development and technical transfer, and manpower training.

Forestry management in the Yangtze River Basin has not only attached great importance to regional development but also has an important influence on the environment and development of the country as a whole. It is our sincere hope that, with the efforts of the Chinese people and with international cooperation, forestry in the Yangtze River Basin will be developed successfully so that it can bring benefits to meet the needs of the present while not compromising the ability of future generations to meet their own needs.

Other shelterbelt systems

The coastal windbreak system

The coastline of mainland China is 18,000km long, and the coastal area includes 195 prefectures/cities/counties in 11 coastal provinces and autonomous regions, covering an area of 25.0 million ha, and involves a population about 100 million (Ministry of Forestry of the People's Republic of China, 1995b; Scientific and Technological Information Center of China, 1991). The coastal area is the major base for the resources of agriculture, forestry, animal husbandry, supplementary production and fishery. But natural disasters befall it frequently and bring unfavourable elements such as strong winds, sandstorms, high tides, droughts, waterlogging, soil salinization and soil erosion. In the 1950s, China had already started to establish a coastal windbreak system with a combined structure of belts, tracts and networks grouped together, mainly to break wind and to fix sand. Among these, the backbone forest belts, as a first line of defence, have a normal width of 100–200m, with a maximum width of 500m. They ran parallel to the coastline, or vertical to the direction of winds, shifting sands and sea waves. As tracts, belts of forests with a high density 4500–6000 plants/ha were established on sand dunes, sandy beaches, sand belts and along the sea coast to fix drifting sand, and their width was usually no less than that of the drifting sand belt. Since the early 1980s, the coastal windbreak has been gradually transformed into an eco-economic type. The shelter windbreak combined well with timber, economic and fuel forest, to provide a coastal windbreak system with multiple functions and high benefits. This gradually developed into a basis for economic forests oriented to forest trade and 6.8 million ha of shelterbelt has been planted, raising forest coverage to 27.2 per cent.

The farmland shelterbelt system in the plains

The farmland shelterbelt comprises the majority of China's shelterbelts. China's farmland regions include the Sanjiang Plain, the Songliao Plain, the Huanghuai Plain, the North China Plain, the plain in the middle and lower reaches of the Yangtze River and the Pearl River Delta. The total area is 113 million ha in these agricultural regions, covering 993 counties, and contains half of the national total population (Ministry of Forestry of the People's Republic of China, 1992, 1993, 1995a, 1995b). From the beginning of the 1960s, the afforestation campaign was centred on the greening of the plains, and a farmland forest network was established with a structure of 2–3 rows of trees along canals, irrigation ditches and by roadsides, in accordance with local conditions. So far, one-fifth of China's crop land has been incorporated under the shelterbelt network. Natural disasters have been effectively controlled, and the stress resistance capability of farmland has been significantly enhanced. China's farmland shelterbelts are developing into an integrated type of multiple purpose forest.

Recommendations and perspectives

In order to achieve long-term sustainability of shelterbelt systems in land use, technical and funding support is critical for its efficient management. The recommendations on technical support, according to different ecological and environmental conditions in various areas, require promotion of the use of high quality planting material, selection of sites for the appropriate species, prevention of forest pests and diseases, and establishment of multi-functional ecological forest systems with combinations of trees with bushes and grasses. Improvement in the composition of tree species and forest types in the shelterbelt systems are needed, increases in the percentage of economic forest and economic tree species should be implemented that will raise the direct value and bring into full play public initiatives for establishing and protecting shelterbelts. Shelterbelt management information and monitoring systems should be set up, as well as a shelterbelt research centre to train technical and operational personnel, speed up the application of research results, and extend nationwide the experience gained in conducting model projects for comprehensive shelterbelt systems. International cooperation and academic exchanges and research should be encouraged, with the introduction of advanced management expertise. On funding support, there should be efforts to increase gradually the direct input from governments at various levels into the development of the ecological forestry programmes. A compensation mechanism should be set up to pay off the ecological benefits according to which those who receive benefits shall pay for them. Financial assistance from enterprises, public institutions, individuals, foreign governments, international organizations and private donors should be sought. In addition, strict enforcement of the forest laws, forest policy and institutional reforms, and adoption of specific regulations and rules to protect and manage shelterbelt systems and prevent illegal destruction should be implemented.

Shelterbelt management should not only pay attention to long-term ecological and social benefits, but must also consider the immediate economic benefits, and timber, commercial and fuelwood plantations should be important components of a protection forest project. With regard to production structure, diversified economy and integrated development should be encouraged. Projects with immediate benefit should be promoted so as to compensate for those with long-term benefits. It is crucial to improve on a large scale the existing networks of shelterbelts, to introduce tree species with greater stability, to increase economic and landscape trees and to find more uses, and to build a multi-functional integrated forestry, agricultural and ecological system so as to guide farmland ecosystems, agriculture and animal husbandry onto a path of sustainable development.

At present, the establishment of China's shelterbelts is developing into a comprehensive system of ecological types. The research work has developed from qualitative description to quantitative analysis, and from single item to a comprehensive project, integrating vegetation (trees and crops), atmosphere and soils into a complete system. New techniques of remote sensing, micro-meteorology, and simulated ecological experiment are being used for in-depth research to reveal the proper structure, functions and mechanism of agricultural benefits from the shelterbelt systems. All these efforts are aimed at developing shelterbelt systems in China.

Agricultural Biotechnology in Southern Africa: A Regional Synthesis

Doreen Mnyulwa and Julius Mugwagwa

The Convention on Biological Diversity (CBD) defines biotechnology as 'any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use'. Defined this way, it clearly emerges that biotechnology is an old science, with many established uses in areas such as agriculture, medicine, forestry, mining, industry and environmental management. The old applications are generally referred to as traditional biotechnology, and in agriculture these have been in use since the advent of the first agricultural practices for improvement of plants, animals and microorganisms (Persley and Siedow, 1999).

The application of biotechnology to agriculturally important crop species, for example, has traditionally involved the use of selective breeding to bring about an exchange of genetic material between two parent plants to produce offspring with desired traits such as increased yields, disease resistance, and enhanced product quality. The exchange of genetic material through conventional breeding requires that the two plants being crossed be of the same or closely related species.

The generations of biotechnology

The progress and development of biotechnology is generally divided into three broad categories, also referred to as generations of biotechnology. This acknowledges that biotechnology is not a new technology, but rather is a continuum of techniques and approaches that have evolved over time.

The first generation. This refers to the phase of biotechnology that was based on empirical practice, with minimum scientific or technological inputs. This phase stretched all the way from 12,000 BC to the early 1900s.

Reprinted from Mnyulwa D and Mugwagwa J. 2005. Agricultural biotechnology in Southern Africa, in S W Omano and K von Grebner (eds) *Biotechnology, Agriculture and Food Security in Southern Africa.* International Food Policy Research Institute and FANRPAN, Washington DC and Harare. Reproduced with permission from the International Food Policy Research Institute, www.ifpri.org. The book from which this chapter comes can be found online at www.ifpri.org/pubs/books/oc46.htm#dl.

The second generation. Developments in fermentation technology, especially during the period between the two world wars, constitute what is generally referred to as the second generation or phase of biotechnology. Major products from this generation were antibiotics such as penicillin and other products such as vitamins and enzymes. Another critical event of this generation, beginning in the 1930s, was the development and use of hybrid crop varieties in the US Corn Belt, which resulted in dramatic yield increases.

The third generation (new biotechnology). The third generation or phase of biotechnology, also referred to as the new or modern biotechnology, is the present one. A turning point occurred in 1953 with the discovery at Cambridge University (UK) of the structure of deoxyribonucleic acid (DNA), which is the molecular carrier of stored information. DNA is a long and winding molecule that is made up of a combination of several chemicals. Four related chemicals in DNA, called 'bases', are lined up in specific sequences, and these specific sequences represent the information that determines the traits, features, characteristics, abilities and functioning of cells within an organism.

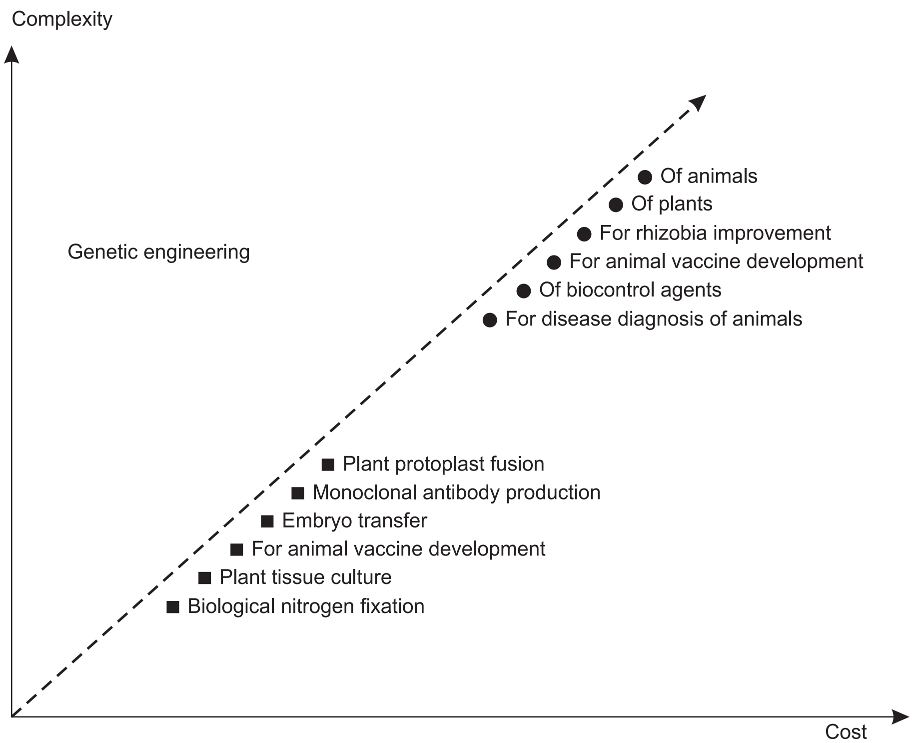
The particular segment of DNA that contains information for a particular characteristic or trait is called a gene. In other words, the genes represent information that is passed on from one generation to the next. It is also important to point out that not all segments of DNA represent information that can be or is passed on from one generation to the next. Because DNA is made up of chemicals that are present in cells where many life-maintaining processes are occurring, the DNA needs to 'protect' itself, and hence some segments of the DNA serve the purpose of ensuring that the DNA remains intact.

The current status of biotechnology research and use in the SADC region

Countries in the Southern African Development Community (SADC) region are employing various forms of biotechnological techniques in their agricultural, environmental management, forestry, medicine and industry efforts, and have been since time immemorial. However, without doubt Africa is the region where biotechnologies are the least developed. There are many different explanations for this situation, but several schools of thought associate it with the perennial economic problems affecting the continent (Sasson, 1993).

Figure 19.1 shows the gradient of biotechnologies in terms of complexity and costs. An analysis of the status of biotechnology in the different SADC countries will be presented and discussed based on this gradient.

From studies conducted by the Biotechnology Trust of Zimbabwe (BTZ) in 2001 and 2002, and studies by other organizations such as the Rockefeller Foundation and International Service for National Agricultural Research, it can be seen that the main area in which biotechnology techniques are being applied in southern African countries is agriculture, with the major thrust being crop improvement. Techniques such as tissue culture are being applied in almost all the countries,



Source: Sasson, 1993

Figure 19.1 *Gradient of biotechnologies in Southern African Development Community countries in terms of complexity and costs, 1993*

mainly because of the less intensive nature of this technique in terms of human and infrastructural resources.

Modern biotechnological techniques, which include genetic engineering, are being employed in a few of the countries, namely Malawi, South Africa and Zimbabwe, and to a small extent in Mauritius and Zambia. Of all these countries, only South Africa has reached the commercialization stage insofar as products of genetic engineering are concerned. The rest are still at the laboratory research stage.

Tied closely to the issue of research is the development and implementation of regulations to monitor the research and products thereof. Only three countries in the region, namely Malawi, South Africa and Zimbabwe, have legal mechanisms for biosafety, that is, the safe development and application of biotechnology. The rest are still at varying stages in the development of their biosafety systems. All countries of the SADC region are signatories to the Cartagena Biosafety Protocol, an addendum to the CBD, which governs safe trans-boundary movement of living modified organisms, among other provisions for ensuring safety in biotechnology.

Table 19.1 gives details on the status of development and use of various biotechnological techniques in the southern African countries.

Table 19.1 *Status of development and use of biotechnology techniques in Southern African Development Community countries, 2002*

Techniques/category	*Areas of application*			
	Angola	*Botswana*	*Democratic Republic of Congo*	*Lesotho*
Tissue culture (TC)	Little is known	Used on a limited basis for root and tuber crops	Little is known	Used in Irish potato production and micropropagation
Genetic modification (GM)	Little is known	Limited research is being done at the University of Botswana. No field trials have been approved	Little is known	None
Fermentation technology	Little is known	Used in the brewing industry	Little is known	None
Marker-assisted selection	Little is known	None	Little is known	None
Artificial Insemination and embryo transfer	Little is known	Used in livestock breeding	Little is known	None
Molecular diagnostics and molecular markers	Little is known	Used on a limited basis in plant and animal disease diagnosis	Little is known	None; serological techniques are still being used
Biological nitrogen fixation	Little is known	Used mainly through integration of legumes in cropping systems	Little is known	Used for legumes only
Manpower training	Little is known	Training is offered in other natural science modules at the University of Botswana	Little is known	Undergraduate and graduate training is done in natural and agricultural science (National University of Lesotho)

Table 19.1 *(continued)*

	Areas of application		
Techniques/category	*Malawi*	*Mauritius*	*Mozambique*
Tissue culture (TC)	Used in disease elimination and micropropagation for cassava, sweet potatoes, Irish potatoes and horticultural crops	Used on a limited basis in sugar cane research	Used in cassava and Irish potato production, micro-propagation and disease elimination
Genetic modification (GM)	At the research level for cassava improvement (virus resistance). *Bt* cotton trials have been conducted.	GM sugar cane is nearing field trials. Awaiting adoption of a biosafety framework	None
Fermentation technology	Used for food and feed production	Widely used in the brewing industry	None
Marker-assisted selection	None	None	None
Artificial Insemination and embryo transfer	Used for cattle breeding	Used on a limited basis	None
Molecular diagnostics and molecular markers	At the research level for use in animal disease diagnosis and diversity studies	Serological techniques are still used for diagnosis	Serological techniques are still being used
Biological nitrogen fixation	Used for legumes only	Used for legumes	Used on a limited basis, for legumes
Manpower training	Training is done in the natural and agricultural sciences (Bunda College of Agriculture). Most of the training is theoretical. No explicit biotech courses are offered	No explicit biotechnology training is offered	Limited training is done in the natural sciences and agriculture (Eduardo Mondlane University)

Table 19.1 *(continued)*

	Areas of application		
Techniques/category	*Namibia*	*Seychelles*	*South Africa*
Tissue culture (TC)	Used in cassava and Irish potato production, micropropagation and disease elimination	Little is known	Active programmes have been developed employing TC techniques for root and tuber crops, ornamental and horticultural crops, and animal vaccine production
Genetic modification (GM)	None	Little is known	Most major universities and research institutions (both government and private) have major projects employing GM techniques. Both crops and animals are covered in the research activities. Insect-resistant cotton and maize and herbicide-tolerant cotton and soybeans are already being grown commercially
Fermentation technology	Used in food processing (small-grain crops)	Little is known	Used widely in food and beverages as well as in pharmaceutical industries
Marker-assisted selection	None	Little is known	Used in maize and small-grains breeding as well as livestock research and development
Artificial insemination and embryo transfer	Used in cattle breeding	Little is known	Used in livestock research, breeding, and conservation
Molecular diagnostics and molecular markers	Serological techniques are still being used	Little is known	Used for plant and animal disease diagnosis
Biological nitrogen fixation	Used for legumes only	Little is known	Used for soil fertility improvement through legumes and inoculants
Manpower training	Limited training is done, but University of Namibia is currently pursuing setting up an MSc programme in biotechnology	Little is known	Specific degree-level training programmes are available at most major universities, with access to state-of-the art resources

Table 19.1 *(continued)*

	Areas of application		
Techniques/category	*Swaziland*	*Tanzania*	*Zambia*
Tissue culture (TC)	Used in Irish potato production and micropropagation	Techniques are employed relatively extensively for root and tuber as well as horticultural crops	Used in micropropagation and disease elimination for cassava, sweet potatoes, Irish potatoes, mushrooms and planting materials
Genetic modification (GM)	None	Limited research is being done, e.g. on virus resistance in bananas. There have been no commercial releases, but trials on GM tobacco were conducted in 2002	Use limited; still at the research level for cassava improvement (virus resistance). Confined trials of *Bt* cotton were conducted in 1999/2000
Fermentation technology	None	Used in the brewing industry and vaccine production	Used for food and feed production
Marker-assisted selection	None	Used in genetic characterization of coconuts, cashews, sweet potatoes, cassava and coffee	None
Artificial insemination and embryo transfer	Used in cattle breeding	Used in livestock breeding and conservation	Used for cattle breeding
Molecular diagnostics and molecular markers	Serological techniques are still being used	Used in plant and animal disease diagnosis	Used for plant and animal disease diagnosis and diversity studies
Biological nitrogen fixation	Used for legumes only	Used mainly for legumes; used on a limited basis for inoculants	Used for both legumes and inoculants
Manpower training	Training is done at the undergraduate level in natural sciences (University of Swaziland)	Training is done in agricultural and other life science courses. A BSc degree in biotech was recently introduced at Sokoine University. The country is also benefiting from the BIO-EARN (East African Regional Network on Biotechnology and Biosafety) programme	Training is done in the natural, veterinary and agricultural sciences (University of Zambia). No explicit courses are offered in biotech

Table 19.1 *(continued)*

	Areas of application
Techniques/category	*Zimbabwe*
Tissue culture (TC)	Used in micropropagation and disease elimination for sweet potatoes, mushrooms, Irish potatoes and horticultural crops
Genetic modification (GM)	Still at the research level, mainly for use in crop improvement for cowpeas, tobacco, maize and sorghum. Confined trials of *Bt* maize and cotton have been conducted
Fermentation technology	Used in food processing, feed and vaccine production
Marker-assisted selection	At the research level for improvement of maize for drought resistance and for small-stock improvement
Artificial insemination and embryo transfer	Used for cattle and small-stock breeding
Molecular diagnostics and molecular markers	Used for plant and animal disease diagnosis and diversity studies
Biological nitrogen fixation	Used for soil fertility improvement for both legumes and inoculants
Manpower training	Specific biotech training programmes have been developed at both undergraduate and graduate levels (University of Zimbabwe, National University of Science and Technology, Africa University)

Biosafety Systems

An analysis of the SADC countries looking at the status of their development and use of policy systems to ensure the safe development and application of modern biotechnology shows that the countries are at different levels. They can be placed into three broad categories: those that have regulations, those that have draft regulations and those that have yet to initiate or are still in the very initial stages of development of such regulations. Table 19.2 summarizes the countries' status.

Global and regional trends in the production of GMOs

Worldwide it is estimated that more than 3 billion people have been consuming GM foods since their commercialization in 1996. The use of GM plant varieties represents the fastest adoption of a new technology according to reports of the International Service for the Acquisition of Agri-Biotech. The total land area devoted to cultivation of GM crops increased from 1.7 million hectares in 1996 to 52.5 million hectares in 2001 (James, 2001). By 1998 some 40 new GM varieties were being cultivated worldwide, mainly in Argentina, Australia, Canada, China, France, Mexico, South Africa, Spain and the US.

The area of GM crops in the developing countries has increased over the years from 15 per cent in 1998 to 25 per cent in 2001, of which 22 per cent was planted in Argentina and 3 per cent in China. China is the only country where public researchers funded by the government produced and commercialized GMOs.

Trends in Southern Africa

Currently it is only South Africa that has commercialized GM crops. Both the commercial and small-scale farmers are cultivating these. Table 19.3 shows figures on the trends of adoption of GM crops in the Makhathini Flats (Kwazulu-Natal Province), the first smallholder farming area to adopt the GM varieties of cotton. GM white maize has been commercialized (2002/2003 season) in South Africa, and this will cause a number of smallholder farmers to adopt the cultivation of GM crops.

Overview of GM use in the SADC region

The use of biotechnology in the medical sciences is generally well accepted. Its use in agriculture is mixed; for example, South Africa is well into the use of GM crops, while the rest of the SADC nations are still behind. Importation policies are not clear, especially because producers from countries like the US do not label GMO products.

Table 19.2 *Status of development and use of biosafety systems in Southern African Development Community countries, April 2003*

Biosafety issue	*Angola*	*Botswana*	*Lesotho*	*Malawi*
Status of development and implementation	There is no biosafety legislation at the moment. The Ministry of Agriculture has initiated discussions on biotechnology and biosafety issues.	There is no biosafety legislation in this country. A process to develop a national biosafety framework was initiated in 2002 with funding from the United Nations Environment Programme (UNEP) and the Global Environment Facility (GEF). The National Coordinating Strategy Agency is the national focal point for biosafety.	A biosafety committee was set up in 2001 within the Environmental Protection Unit to initiate drafting of legislation. Very limited capacity for risk assessment	Has legally binding legislation on biosafety. A national biosafety committee was appointed, though the country has limited capacity for risk assessment.
Use of biosafety system in regulation of work on or use of genetic engineering (GE)	It has been reported that GE grain imported by Namibia in 2001 was milled in Angola. Namibia's draft legislation guarded against contamination of the environment. Angola had and still has no regulations	As indicated, there are no mechanisms in place to regulate GE and its products. The dependence of the country on agricultural produce from South Africa is a cause for concern.	There have not been any official reports of requests to conduct trials or import GM products. Absence of a biosafety system complicates the situation. However, some food products, especially from South Africa, are suspected to be GM.	An interim committee was consulted in the debate on whether Malawi should import GM food aid or not. Malawi accepted GM maize, with no conditions set.
Urgent requirements	Regulations, capacity building, public awareness	Development of a legal framework, capacity building, public awareness and participation	Garnering support from policy makers, development of regulatory framework, capacity building, public awareness	Raising awareness of new legislation among stakeholders, capacity building

Table 19.2 *(continued)*

Biosafety issue	*Mauritius*	*Mozambique*	*Namibia*	*Seychelles*
Status of development and implementation	Has a GMO bill that requires setting up a national biosafety committee (NBC)	Set up a committee within the Ministry of Environment to come up with interim legislation on biosafety. Legislation still being developed.	Has a national biosafety committee (the Namibian Biotechnology Alliance) and draft legislation. Also has very limited capacity for risk assessment.	Discussion of biotechnology and biosafety issues has only just started in this country to whose economy agriculture contributes only marginally. The main worry is that the country is a net food importer.
Use of biosafety system in regulation of work on or use of genetic engineering (GE)	Officially, no GE products have entered the country. The NBC is tasked with monitoring the registration and movement of GE products in the country. A locally developed GM sugar cane variety is awaiting release.	Has already officially received GM maize under the condition that it has to be milled before distribution to consumers. A framework is still needed to ensure effective monitoring of GM products.	Accepted milled GM maize in 2000. Rejected GM maize in 2002, and instead received food aid in the form of wheat, as per a recommendation by the national biosafety committee.	Importations of foodstuffs have been handled under the existing food and food standards regulations
Urgent requirements	Regulations, capacity building, public awareness	Development of regulatory framework, capacity building, public awareness	Finalizing processes for regulation development, capacity building and public awareness	Awareness raising, regulations, capacity building

Table 19.2 *(continued)*

Biosafety issue	*South Africa*	*Swaziland*	*Tanzania*
Status of development and implementation	Has had a legally binding GMO Act since 1997; also has the institutional framework to administer the act. The country has a number of both public and private laboratories adequately equipped to do GE work. Has more than 110 plant biotech groups, more than 160 plant biotech projects, and more than 150 trials.	Set up a committee within the Environmental Protection Agency to come up with interim legislation on biosafety. Legislation still being developed.	A national biosafety coordinating committee was set up under the government's Division of the Environment in November 2002. This activity is taking place under the UNEP-GEF project.
Use of a biosafety system in the regulation of work on or use of GE	Already has a number of GE research work projects and products on the ground, including commercial cultivation of GM horticultural crops, cotton and maize by smallholder farmers	Has already officially received GM maize under the condition that it has to be milled before distribution to consumers. *Bt* cotton and maize are currently being grown by farmers in parts of South Africa bordering Swaziland, and thus there is fear for possible contamination.	Tanzania has been a port of entry for GM maize provided as food aid to some countries in the region. Consignments were handled under the existing phytosanitary regulations.
Urgent requirements	Review of legislation, public awareness and participation	Obtaining stakeholder support, especially from policy makers, as well as regulation development	Regulations, resource mobilization, public awareness

Table 19.2 *(continued)*

Biosafety issue	*Zambia*	*Zimbabwe*
Status of development and implementation	Has draft legislation and a national biosafety committee. Limited capacity for risk assessment. Currently in the process of coming up with a national biotechnology strategy.	Has a legally binding biosafety system, which includes a biosafety board and its secretariat, as well as biosafety regulations and guidelines. Has some laboratories, which have the capacity to detect genetically modified organisms (GMOs).
Use of a biosafety system in the regulation of work on or use of GE	An interim committee recommended rejection of GM food aid (July 2002). A case of unapproved trial of GM maize was reported in 1999 (personal communication with Monsanto, 2001).	Two field trials were approved in 2001, for *Bt* cotton and *Bt* maize. No commercialization has been approved as yet. Assessed applications for importation of GM maize; importation granted with conditions.
Urgent requirements	Enactment of legislation, capacity building, public awareness	Review of current legislation, capacity building, public participation in decision making processes

Source: Based on Mnyulwa and Mungwagwa, 2002, but updated through continuous interaction with partners

Table 19.3

Season	*Percentage of farmers cultivating* Bacillus thuringiensis (Bt) *cotton*

1999/2000	60
2000/2001	71

Public Dialogue, Public Awareness and Policy Responses

Background

Proponents of GM technologies cite several potential benefits that can accrue to society. These benefits include enhanced taste and quality of foods; nutritional enhancement of foods for chronically malnourished populations; reduced maturation times for crops, leading to labour savings; and enhanced tolerance of biotic and abiotic stresses for crops, leading to reduced dependence on herbicides and pesticides. But these perceived benefits are not uncontroversial.

As a result of the intense debate and controversy surrounding the development and use of GMOs it is important for countries to engage in wide stakeholder dialogues in order to ensure that people are equipped to make informed choices. The public ought to participate even in the development of frameworks for regulation of GM research and development work. The main reasons for public awareness of and participation in the development of national biosafety frameworks (NBFs) are to promote participatory decision making and involve all sectors of the society, to bridge the differences between various parts of society concerning the safe use of living modified organisms (LMOs), to ensure the use of an inclusive process involving all stakeholders, to share a common vision and purpose, to promote improved decision making based on information, and to promote transparency in the decision making process. It is important to note that the development of NBFs goes beyond the creation of a document. It inevitably encompasses wider issues about the role of biotechnology and requires ongoing participation in biosafety processes after regulations have been developed. The process itself calls for commitment and the creation of an appropriate environment to access participatory mechanisms, capacity building, information dissemination and strategies for involvement of all stakeholders.

Participation in biosafety is prescribed in Article 23 of the Cartagena Protocol on Biosafety (United Nations Environment Programme, 2002):

> Public awareness and participation:
> 1) Parties to the protocol shall:
>   a) Promote and facilitate public awareness, education and participation concerning the safe transfer, handling and use of living modified organisms in relation

to the conservation and sustainable use of biological diversity, taking also into account risks to human health. In so doing Parties shall cooperate, as appropriate, with other states and international bodies;

b) Endeavour to ensure that public awareness and education encompass access to information on living modified organisms identified in accordance with this Protocol that may be imported.

The Parties shall, in accordance with their respective laws and regulations, consult the public in the decision making process regarding the living modified organisms and shall make the results of such decisions available to the public, while respecting the confidential information in accordance with article 21.

Participation is crucial in the analysis of the issues, in decision making and strategic planning, in implementation, and in monitoring and evaluation. Stakeholders can be defined as people from government agencies and the private sector, groups or individuals whose lives and interests could be directly or indirectly affected, and bodies, groups or individuals with particular knowledge that could be called upon.

Public awareness was defined by the participants of a UNEP workshop on risk assessment and risk management held in Namibia in 2002 as a process of providing universal access to information (providing balanced information in terms of pros and cons), enlightening the public, and thereby providing for informed participation. *Public participation* was defined as involving stakeholders (at all levels of society) in decision making processes (giving everyone a chance to express their views) and taking their suggestions into consideration in making a decision. Public awareness and participation are needed for:

1 consensus building on issues that affect people directly or indirectly;
2 ensuring implementation of the decision;
3 building transparency and accountability;
4 facilitating informed participation;
5 achieving a better position from which to take action;
6 facilitating inclusiveness;
7 providing balanced information in terms of pros and cons;
8 harmonizing institutions that provide awareness activities;
9 removing bias;
10 building a sense of ownership and collective responsibility;
11 building stakeholder confidence;
12 bridging the knowledge gap;
13 ensuring sustainability;
14 minimizing conflicts;
15 creating a platform for action; and
16 attracting attention and interest.

Status of public awareness in the SADC region

Different countries in the SADC region have sought to promote and facilitate public awareness and participation in the design and implementation of their NBFs. Different tools and approaches have been suggested by various efforts (see United Nations Environment Programme, 2003a). Participants at a UNEP-GEF Namibia workshop on risk assessment, risk management, public awareness and public participation for sub-Saharan Africa held in Namibia in 2002 proposed an action plan for enhancing public awareness and participation in the southern African region (see United Nations Environment Programme, 2003a).

It is the responsibility of each party to determine the combination of the proposed tools suitable for their specific situation. In most countries in the region the lack of biosafety frameworks is partially attributed to these countries' lack of awareness at various levels of the importance of both the technology and the need for biosafety policy. Table 19.4 summarizes the levels of biotechnology awareness in the SADC countries, including the awareness-raising tools and approaches being employed in the different countries.

The challenges of public participation

The public awareness levels shown in Table 19.4, together with the efforts to arrive at such levels, are confounded by many factors, some of which are discussed in this section.

Commercial confidentiality. One of the major challenges of public participation is defining the limits of confidentiality for the provision of information to the public. A statute on access to information might be needed, or the responsibility for deciding what represents confidential information might be given to the national governments in consultation with the companies concerned.

The costs of various levels of participation. These costs need to be planned for and addressed during the planning period. They have to be dealt with in the context of the limited human, infrastructural and financial resources of most of the countries.

The diversity of the various developing countries' farming systems and other cultural and social factors. This diversity makes it difficult to come up with a common framework for the involvement of stakeholders in the decision making processes.

High science. How does one simplify highly scientific information to facilitate and increase the comprehension of the concepts by the general public, the majority of whom are illiterate? Challenges exist regarding how to effectively communicate science to a public of such a dynamic background as obtains in most of the developing SADC countries, where stakeholders have different priorities to address and

Table 19.4 *Levels of biotechnology awareness and public awareness strategies in Southern African Development Community countries, March 2003*

Country	*Levels of biotech awareness*	*Strategies used for information dissemination and awareness raising*
Angola	Low (assumption)	Little is known about strategies
Botswana	Low overall	Uncoordinated and sporadic activities, mainly announced through newspaper articles and led by scientists and to some extent the consumer movement
Democratic Republic of Congo	Low (assumption)	Little is known about strategies
Lesotho	Low overall	A few sporadic activities, mainly driven by scientists
Malawi	Average among scientists, low among other stakeholders	Discussions in the form of workshops and meetings, mainly coordinated by Bunda College and the National Biosafety Committee. Other tools are mainly sporadic debates and responses via the local press.
Mauritius	Low overall	A few, largely sporadic, activities coordinated by the National Biosafety Committee
Mozambique	Low, even among scientists	Still largely uncoordinated and reactive efforts for coordination through the Africa-Bio and Southern African Regional Biosafety programmes
Namibia	Average to low	Some activities coordinated by the National Biotechnology Alliance, the farmers union, and the consumer movement
Seychelles	Low (assumption)	Little is known about strategies
South Africa	Average among the affluent groups but low among smallholder farmers and general consumers	Formal media and informal channels (including websites, leaflets and public debates) sponsored by a number of non-governmental organizations and companies such as Africa-Bio, Biowatch, SAFeAGE (South African Freeze Alliance on Genetic Engineering), A-Harvest, and Monsanto. Notices of application for trials or release of genetic engineering (GE) products are published in the government gazette to solicit public comments.
Swaziland	Low overall	A few sporadic activities, mainly driven by scientists
Tanzania	Average to low	A few activities, some coordinated by the National Biosafety Committee, some by scientists, and some by the Commission for Science and Technology

Table 19.4 *(continued)*

Country	*Levels of biotech awareness*	*Strategies used for information dissemination and awareness raising*
Zambia	Average to low among scientists, low among the rest	A few, largely uncoordinated and irregular, activities such as debates and discussions organized by the National Biosafety Committee, the National Farmers Union and the consumer movement
Zimbabwe	Average among the scientists, low among stakeholders	Advertisements in the government gazette soliciting public comments. A number of organizations engage in information dissemination (e.g. the Biotechnology Trust of Zimbabwe, the Biotech Association of Zimbabwe, the Consumer Council, the Pelum Association, COMMUTECH (the Community Technology Development Trust), the Intermediate Technology Development Group, and the biosafety board, among others. The main channels used include workshops, seminars, debates, information brochures, radio and television discussions, etc.

Source: Based on Mnyulwa and Mugwagwa, 2002, but updated through continuous interaction with partners

have to deal with a language barrier (explaining science in local languages is impossible in most cases). It is noted that dialogue requires honesty, openness, transparency and inclusiveness, along with mutual respect and an absence of mistrust. The starting point for dialogue should be the premise that the public has valid views that need to be voiced and understood, taking into account room for variance. Public participation has to be based on access to information, and it is necessary for national governments to facilitate the packaging of information in a way that meets the stakeholders' needs.

External influences. Many such influences affect decisions taken by developing countries on the commercial use, risk assessment, and risk management issues related to LMOs. Trade in GM crops and products will be subjected to the international agreements signed by the member states. The majority of the developing countries, SADC countries included, are parties to the World Trade Organization (WTO), and thus the protocol is supposed to allow free and equitable trade. Yet the following issues need to be taken into account:

- GMOs require special clearance mechanisms to allow developing countries to make a choice – to accept or reject GMO goods and not be bound by the WTO provisions alone.

- An exporting country is not liable for damage and environmental pollution due to GMOs.

National laws are needed on labelling both the grain and seed and any blended products. Experience so far has shown that the use of GMOs in developing countries is dictated by trading partners such as the European Union.

The murky interface (food aid, politics, science, and regulations). A number of public concerns resulting from the use of modern biotechnology relate to their impact on trade, the environment and health. Says David Dickson of SciDev.Net: ‘On closer inspection, the decision by Zimbabwe and Zambia begins to lose some of its apparent naivety. The real fear officials of these countries are said to have explained to the officers of the World Food Program, is not the health danger that these foods are said to cause. Rather it is that if GM maize seed is planted rather than eaten, there could be “contamination” of local varieties, and this will mean that the agricultural produce of these two countries, including beef fed on the crops, could no longer meet the “GM free” criteria demanded by European Markets’ (www.scidev.net/archives/editorial/comment28.html). A study by Environment and Development Activities in Zimbabwe after the 1991/1992 drought revealed that about 20 per cent of the smallholder farmers from some selected districts of Zimbabwe had retained the yellow maize grain provided as drought relief to use as seed. So the danger that GM maize grain will find its way into the seed system is real.

Most of the developing countries’ positions are compromised by those of their trade partners, whether Europe or America. The conflicting positions of the two major trading partners of most southern African countries has greatly influenced the current positions adopted by the various nations.

The US, one of the major suppliers of food relief, has been commercially growing GM crops for the past 5 or 10 years, and they do not segregate or label these products. The political dimension of the debate over southern African hunger and GM maize is that the US appears to be using the current famine as a cover to promote acceptance of a technology ‘enthusiastically embraced by its own corporations, while remaining widely distrusted in Africa’ (Dickson, 2002). The US has shown frustration with African critics of its food offer, and has also shown reluctance to provide funds for processing the maize, conditions that have further fuelled the political dimension. A statement in early 2002 by one US official that ‘beggars cannot be choosers’ has further haunted the humanitarian effort.

The absence of regulations for monitoring the movement of GM material in most of the affected countries is another problem. Personal communications with some authorities in Zambia have shown that although the trade, food safety and environmental dimensions have been mentioned, one salient but important dimension has not: that of regulations. The affected parties have feared that lack of a legal framework would frustrate any efforts to ensure monitored and controlled movement of the GM maize once it was released to the population. The situation in Zimbabwe has been different because regulations were in place already, and

Malawi (then) was at an advanced stage in the development of its regulatory framework; hence it has been possible for decisions to accept the GM maize to be made.

The situation that has been faced in southern Africa points to the reality that countries have to accept regarding the impact of modern science on society – that it involves a complex of scientific, economic and political factors that cannot easily be reduced to any single dimension (Dickson, 2002).

The Public Awareness Effort in Southern Africa – A SWOT Analysis

Below is a strengths, weaknesses, opportunities and threats (SWOT) analysis (Table 19.5) of the public biotechnology awareness effort in southern African countries. This analysis is adapted from results of the UNEP-GEF workshop held in Windhoek, Namibia, in November 2002.

Recommendations

Mindful of the situation prevailing in the SADC region with respect to biotechnology, and cognizant of the role that the technology can play in agriculture and food security issues, we recommend that the following needs be addressed.

Development of the capacity to make decisions

One critical issue that emerged from the 2002 debate on food security vis-à-vis the use of GM maize as a food aid was that the majority of countries in the SADC region lacked the regulatory and scientific structures necessary to take decisive steps. During the BTZ's regional consultation on the status of development of biosafety systems in eastern and southern African countries, it emerged as a major sticking point that most countries did not prioritize development of regulatory structures for biosafety, mainly because of the low level of biotechnology research and development activities in their countries. If the lessons drawn from the 2002 GM food aid debate are anything to go by, countries in the region are best advised to put regulatory and scientific monitoring mechanisms in place, because the GM products in the region are not the products of research efforts in the region, but rather are products introduced from elsewhere. The scenario is the same as that for products of most other technologies, but the need for regulations remains critical. The GM debate underlined the fact that in a globalized economy the development of regulations is a necessity, not a luxury.

The development of scientific and infrastructural capacity is not an overnight activity. Given the varying levels of capacity and resource endowment in the countries

Table 19.5 *Strengths, weaknesses, opportunities and threats analysis of public awareness and public participation in southern Africa, November 2002*

Strengths	High literacy level
	Political will (many countries in the region have signed the Biosafety Protocol)
	Common official language, facilitating information dissemination
	Existing administrative structures
	Information-sharing structures
	Existing human resources (biotech specialists, etc.)
	Relevant legislation and policies
Weaknesses	Limited programmes on and capacity for modern biotechnology
	Lack of policies on biotechnology and biosafety
	Ignorance of biotechnology, which impedes the dissemination of information
	Lack of sustainable funding
	Science illiteracy
Opportunities	Existing public awareness and participation programmes that can be used to disseminate information, e.g. HIV/AIDS awareness programmes
	Decentralized system of governance
	Availability of UNEP-GEF funding
	Existing subregional programmes (SADC)
	Innovative financial instruments that could be used to generate additional funds for programmes in the form of taxes, levies and other fees
Threats	Lack of networking among scientists and with other political and civic leaders
	Lack of communication between scientists and other interest groups such as sociologists, politicians and civil society

Source: United Nations Environment Programme, 2003b

of the region, mechanisms for collaboration and the development of synergistic relationships need to be put in place for countries to be able to pool their resources. Through the SADC and regional as well as national governmental and non-governmental organizations with activities in the areas of agriculture, the environment, and biotechnology and biosafety, activities can be implemented for the development and strengthening of national and regional capacities that will enable informed decision making on GM products. Arrangements for the transfer of technology and expertise should also be entered into with institutions within the region and beyond that can provide such expertise. Individual countries and the region should place an emphasis on developing their own capacity to do the work so they can become self-sufficient in the long run.

The SADC countries should also be cognizant that genetic engineering is building on the achievements of other accepted and established techniques such as tissue culture, molecular biology, fermentation technology and so on. Countries need to develop a capacity for these techniques, not necessarily to use them as a foundation for genetic engineering, but to exploit them and assess whether some of the agricultural production constraints can be solved using such technologies. Examples abound from Colombia, India, Kenya and Zimbabwe, where tissue culture programmes have been successfully implemented to provide sufficient quantities of high-health status planting materials for crops such as bananas, yams, cassava and sweet potatoes.

Identification of regional needs and priorities

For the region and individual countries to realize some of the benefits to be derived from the employment of modern biotechnology techniques, they need not only to develop regulatory and scientific capacity, but also to identify needs and priorities for intervention at national and regional levels. Priorities would include targeting crops or animals for the research efforts, along with traits to be researched (drought tolerance would be an obvious choice) and the human and infrastructural capacity needs of the countries and the region. Genetic engineering technologies invariably need substantial financial investment, and the SADC countries would best be advised to invest in areas in which they have sustainable competitive advantages or in areas that address their priority food security needs.

Creation of an enabling environment for research about or use of biotechnology products

The development and implementation of regulations is one avenue for creating an enabling environment for biotechnology research and development as well as for the use of products of genetic engineering. The SADC countries need to develop appropriate biosafety systems for monitoring and controlling biotechnology activities in them. Given that the region already has three countries with legal biosafety systems, experience-sharing mechanisms can be put in place and employed so countries can learn from each other about the development and use of such systems. Discussion among policy makers needs to be stepped up so as to garner the necessary political will. For example, in Zambia efforts to put policies in place are thwarted not only by lack of funding and scientific expertise, but also by lack of political will. This certainly is the case in most of the countries of the region.

Stakeholders need to develop strategies for ensuring that national governments prioritize policy development and investment in infrastructural and human capacity for biotechnology activities, and at least some measurable capacity for risk assessment and risk management. In a 2001/2002 eastern and southern African study on the status of development and implementation of biosafety systems conducted by the BTZ, one of the major findings to emerge was that the source of information most trusted by the lay public was one to which local researchers would have made a contribution. One way to achieve this end is to raise the general level of discourse about biotechnology issues both in the individual countries and at the regional level. With an increased awareness of the potential dangers and benefits of genetic engineering technology, policy makers will be in a better position to see the need to develop the necessary legislative frameworks. Awareness also needs to be raised in the general population of the SADC region because people have a right to know whether they should consume certain products. In addition, transparency and trust need to be developed among the private sector, local researchers, national governments and all stakeholders in the region with respect to the real hazards or benefits presented by genetic engineering technology.

Harmonization of national and regional policies

One major lesson from the food aid debacle is that the countries of the SADC region need to harmonize their legislation in order to facilitate smooth movement and transit of food materials. This harmonization should encompass issues such as standards, risk assessment and risk management procedures, prior informed consent requirements, information and documentation requirements and other issues. In essence the harmonized policies should facilitate the development of procedures for approval of the use and movement of products in the region.

Conclusion

The SADC countries are at different levels in the development and application of biotechnology as well as systems to govern the use of this technology. This scenario should be exploited to ensure that all countries attain a certain minimum level of technical and regulatory capacity, especially for monitoring the development and use of GM technologies and the products thereof. It is crucial for all the countries in the region to realize that they need each other, especially given the increasingly globalized economy and the fluid nature of national boundaries, as well as the limited capacity to monitor cross-border movement of materials. Adequately equipping the general public, especially farmers, will go a long way toward building self-monitoring and -policing mechanisms that will complement efforts by regulatory authorities to limit the unintended spread of GM products in the environment. An informed society will also influence the national research agenda, thereby ensuring that the constrained research and development resources of countries in the region are used to address priority issues. Little is known about the existing institutional framework within which GMO legislation and regulation are likely to be implemented, especially in rural areas. Several questions therefore remain unanswered. For instance, what roles are played by the national, provincial and local governments in the various countries? What scientific testing infrastructure exists to implement regulations? What are the existing leadership structures, especially in rural areas? To what extent will uninformed smallholders rely on opinions, information and advice from village-level leaders in making their choices? What problems and opportunities will result from using the rural governance already in place as a coordinating mechanism for spreading information? What is the degree of transparency and accountability in implementing agencies?

Appendix: Tools for Participation, Consultation, Information and Education

The following tools have been adapted from United Nations Environment Programme (2003b) and from the author's workshop notes.

Tools for participation and consultation

There are a number of strategies or approaches that can be used to engender public participation in discussion on biotechnology issues. Some of these are as follows.

Enabling legal frameworks. Laws on public participation or on rights to information facilitate meaningful public involvement in biosafety decision making.

Routine opportunities for public comment. In many countries, applications for regulatory approval are published in a register with opportunities for public comment as a matter of routine. Although this methodology is commonly used in developed countries (for instance, in Canada, the Netherlands and the UK), it may be especially useful in developing countries, where there are usually limited resources to facilitate participation.

Multilevel consultations. In some countries, public consultations on different aspects of the biosafety framework have taken place at the national level. For example, consultations were held in Zimbabwe to decide whether to accept GM food aid and, once the decision was made to accept it, how to handle the products.

Independent public inquiries. Independent bodies can be designed to facilitate assessment of the risks and benefits of a technology considering broad public interests. These bodies, if well constituted, can target the particular needs of indigenous groups.

Independent advisory committees. The authority and credibility of such bodies depend heavily on their independence of the government and the way they are constituted, that is, the extent to which they include the views of non-scientists and represent a broad spectrum of stakeholders. These are the tools used by most of the SADC countries, such as Malawi, South Africa and Zimbabwe. In some cases these are complemented by advertisements in either the government gazettes or the local press soliciting comments from the public.

Ongoing oversight and evaluation. Stakeholder bodies, such as the African Biotechnology Stakeholders' Forum, can be set up to review biosafety procedures on an ongoing basis.

A bottom-up participatory process. Participatory processes facilitated by credible and experienced non-governmental organizations can help stakeholders at risk of being left out by the government-led consultation processes. Examples include the Citizens Jury facilitated by the Intermediate Technology Development Group in Brazil, India and Zimbabwe.

These tools can be used in combination to facilitate the all-inclusive participation of stakeholders in the decision making process. The challenges presented earlier in this chapter hinder such effective participation in most developing countries.

Tools for information and education

The identification of information gaps through surveys is a good starting point for any awareness and education initiatives. Information collected through these means would help a country's government in the development of a public information campaign using the following tools.

Informal means of disseminating information. Websites, leaflets, advertisements and telephone helplines can be used to explain biosafety processes and how stakeholders can be involved in information dissemination. These can even be translated into local languages. The BTZ has been using some of these methodologies in disseminating information to the rural poor.

The established media. Newspapers, radio and television provide useful routes for informing the public about biotechnology and biosafety regulations. These can be used to educate or inform the public about GMOs. Advertisements can also be used to get feedback on proposed releases of GM products.

Sustaining Cultivation

M. Bell

'You're missing something.'

Dick Thompson and I were sitting at his kitchen table, a well-thumbed copy of the first draft of this book in a stack between us. Dick noted the flash of alarm that passed across my face.

'I like the book. Don't get me wrong. I like it a lot. But at least when you're talking about me, there's something you're missing.'

'What's – ' I started to ask.

'Get along but don't go along.'

This is a phrase that Dick says he heard one day when cleaning a hog waterer on his farm, when no one else was around.[1] It's long been his motto, and he repeats it at almost every event he speaks at. I had clean forgotten about it, I suppose because I had never really underlined it in my mind. It seemed to me an interesting but quirky turn of phrase.

'Get along but don't go along. It's what your book's about.'

He blazed those clear blue eyes at me. I met them for a moment, and then turned away. Then, suddenly, I got it. Finally. Dick saw his meaning land, and his face spread with a three-hundred-acre grin.

He was right. Get along but don't go along is Dick's way of saying, in just six words, something that has taken me nearer to a hundred thousand to say. The phrase neatly captures the tensions between modernism and postmodernism, difference and engagement, stability and change, that the Practical Farmers of Iowa (PFI) farmers seek to resolve. Get along: Here Dick means both getting along with others and getting along in the world. He means to emphasize the importance of community and dialogue as well as the importance of achieving one's practical needs, and how these are interconnected.[2] Don't go along: Dick's point here is not that one should never do what others do, nor that one should, solipsistically, disregard what others have to say. Rather, his point is that one shouldn't do it just for the sake of getting along. In the terms I have been using in the book, just going along would lead to monologue and monologic power, to the suppression of difference and

Figure 20.1 *The view from Highway 71, north of Audubon, Iowa. 2001*

of dialogue's creative power. Dick's motto instead stresses the value of retaining and encouraging difference as *part* of getting along, as part of good relations and the achievement of practical outcomes. Falsely treating all our circumstances as the same leads to both alienation and irrelevance. Consensus is not necessary for getting along. Dialogue is, and for dialogue we need to retain a measure of difference if we are to find interest in what others have to say, and thus cultivate new knowledge as we cultivate their interest in and commitment to what we too have to say.

Which is just what PFI tries to cultivate. Their vision of sustainable agriculture is that it brings people together in dialogue – bouncing ideas off one another, testing propositions against the practical needs of growing food and feeding people in ways that protect the environment – keeps communities vital, and yields secure incomes. PFI does not offer its members the seductive comfort of final answers. Silver bullets are bullets just the same, no less hazardous for their gleam. PFI gives its members people to talk to and a means for comparing practical circumstances, ever adapting others' words to their own thoughts and offering their own words back for others to chew over, to reshape in light of their experiences, and to give back to others once again. It is not a process of adoption-diffusion. It is a process of *adaption*-diffusion.

The draw of monologue, of adoption-diffusion, of the Big Ag way should not be underestimated, though. Like the farmer at the wheel of a big green machine, monologue can give those who accept it a feeling of great power, even though the tractor is something that the farmer did not make and could not make, but merely switches on. It is a pleasure of power, not of control. That is to say, it is a borrowed power, an identity on loan. Although it is borrowed, in an uncertain world many feel they can hope for little more.

Moreover, most farmers find themselves trying to live on borrowed time with this borrowed power. So many acres, so little time. The speeding of the treadmill associated with the Big Ag way is itself a structure of monologue, encouraging farmers to seek the quick answers, the readily available answers, the silver bullets, even if one has a slightly uneasy feeling about the shooters of those bullets. No one can rely on their own experience for everything. We simply don't have time to reinvent the many wheels of our lives. We all have to rely on what others tell us. It's inescapable, unless your plan is to stay in bed for the rest of your life. But the problem gets worse and worse the faster the treadmill spins. And given the local intensification of this treadmill through the farmer's problem, farmers are increasingly less likely to look to their neighbours for answers, lest either party gain an advantage over the other thereby. Instead they turn to the monologic answers that the treadmill itself provides (only sending it spinning all the faster). The Big Ag phenomenology of doing agriculture thus becomes as well a phenomenology of knowing agriculture, of the cultivation of knowledge, of the cultivation of the ignorable, of the cultivation of the self, in this case a largely monologic self.

Cultivating oneself within the monologue of Big Ag does not ultimately ease the lives of most farmers, despite its lure of easy answers. The bankers of borrowed power and borrowed time occasionally call in the loans – not every year, and not on every farmer. But there are payments to be made here, even if they are not in the currency of money alone. This is a deeply disorienting experience for those who have little connection with other conversations of life and self.

To change metaphors, the structures of agriculture are a tough ride, and a lot of farmers get bucked off. It's a real shock when it happens – what I have called a phenomenological rupture. When you're flying through the air, everything you know and do and are comes suddenly into question. Most farmers hit the dirt in a bit of a daze, get up, dust off and see little else to do but to try to get back on the rampaging horse, if they can manage to get a foot in the dangling stirrup and with a mighty heave swing their way back up onto the saddle. And if they can't …

But while you're flying through the air, if the winds are right, you may hear, at just the right moment, of a safer way to land on the rodeo dirt, and of a whole different way to ride when you dust off and get back up. (Maybe you'll even hear of a different, gentler horse.) Not every farmer does. But when you're flying through the air, you listen to the voices in the crowd like you never have before. This moment of phenomenological rupture can actually be a kind of opportunity. So many of the sustainable farmers we interviewed described their decision to change practices as a sudden event. Given the connections between the structures of doing and the structures of knowing, and given the connections of these to the structures of self, there is so much that has to change that very often it needs to be all changed more or less at once – if it is to be changed at all.

PFI is one of those voices in the crowd, and it is a voice with a distinctive manner of speaking. It is a dialogic voice. It is a voice that tells you that you don't have to go along to get along. It is a voice that the farmers of PFI have come, not to adopt as their own, but to adapt to their own.

Farming isn't easy for the members of PFI either. There is still plenty of bucking with the horses they ride as well. Some PFI members eventually wind up leaving the rodeo of farming too. Despite all the environmental, economic, social and possibly health benefits of what they do, the honest truth is that many of them fail. In fact, several of the PFI farmers that appeared in earlier chapters are no longer farming. Roger. Raelyne. Wendell and Terri. I don't know of a survey comparing the survival rates of sustainable and conventional farms, but my impression is that it's much the same for both, although possibly on average sustainable farms survive somewhat longer. Several PFI members I asked about this agreed. If there is a difference in survival rates, it is not so significant that, without a statistical survey, it jumps out at even those closely familiar with the matter.[3]

Sustainable farmers face several disadvantages in the farming rodeo. To begin with, they often start from a position of financial weakness. As we saw in Bell (2004 Chapter 6), economic factors often act as the phenomenological shock that opens farmers up to the possibility of sustainable farming. Such farmers may find themselves just too banged up financially to regain a secure seat in the saddle, although sustainable practices may enable them to stay 'in' farming a few more years. Also, as sustainable farmers tend to farm fewer acres and buy fewer outside inputs, such as machinery and chemicals, ironically they will be more likely to find themselves beholden to banks and merchants, rather than having the banks and merchants equally beholden to them. Because sustainable farmers spend less and borrow less, the balance of beholden-ness is more often tipped against them, making it more probable that the banks and merchants will call in their accounts.

Another disadvantage sustainable farmers face is with the structure of agricultural subsidies. The average Iowa farmer does quite nicely in this respect, with that annual subsidy cheque of $22,400 per farm between 1999 and 2001.[4] But averages disguise a lot. Some 72 per cent of Iowa's farm subsidies go to just 20 per cent of the farmers.[5] Smaller farmers usually get a much smaller check, and big farmers a bigger one. It might seem obvious that smaller farmers would receive less, but the subsidy system is often defended as the saviour of small farms. Moreover, small farms typically receive lower subsidies per farm acre than big farms, particularly when the small farms produce something other than corn and soybeans, corn and soybeans, and corn and soybeans, the two main subsidized commodities in Iowa. Fewer acres and different products being two of their typical characteristics, sustainable farms tend to lose out substantially on farm subsidies.

Take Jon and Heather, for example, small-scale beef farmers. They have been getting about $6000 in annual subsidies recently, less than a third of the average per-farm subsidy rate in Iowa.[6] But they have a 320-acre farm, which is near the Iowa average of 344 acres. If they received the Iowa per-acre average, their farm would have averaged about $20,837 in subsidies from 1999 to 2001. Jon and Heather didn't get that because they mostly grow grass and hay for their organic, free-range beef herd – grass and hay because that's essential for free-range production and because they want to limit erosion-prone and chemical-hungry crops like corn and soybeans. A few acres of their steepest land are enrolled in the Conservation

Reserve Program, a government programme for keeping the most erodible land out of row crops. They got about $1000 in annual subsidies for that. And they do grow a few acres of corn, plus some wheat and sorghum, both unusual crops for Iowa. They got about $5000 a year for that. But they missed out on an additional $14,837 a year of support that a more conventional operation of their size would have got.

Given that they favour big farms and not agronomic efficiency; given that they encourage overproduction and not soil conservation and environmental protection, in most circumstances; given that they total an awful lot of money devoted to at best dubious outcomes for the public good; given all this, many have long proposed the restructuring of farm subsidies. At the time of this writing, there is considerable hope among those concerned about sustainability that we may have just taken a large step in the right direction with the passage in 2002 (and the partial funding in 2003) of the Conservation Security Program (CSP). This hotly contested title in the 2002 Farm Bill would pay farmers for a whole series of green enhancements to their operations, from building soil-control structures to encouraging wildlife. It's a manifestation of what some observers of agriculture call 'multifunctionality' – the idea that the purpose of agriculture should go beyond the single-minded one of ever-increasing food production. Rather than paying farmers to do only that, through our food expenditures and through the structure of subsidies, we should pay farmers to do some important things that are not directly included in the price of food – things like conserving soil and providing wildlife habitat. The CSP program would pay individual farms up to $45,000 a year to green their operations, based on a tiered system with three levels of enhancements. The CSP, many people hope, is the breakthrough in farm structure that sustainable farmers have been waiting for.[7]

But others are not so optimistic. The CSP's structure turns out to be very complex. Many of the small farmers who have looked into it have despaired of keeping up with the paperwork necessary to sign up for the programme and to document compliance with it. Larger farms are more likely to be able to hire outside help to sort through its tangle of rules. Also, at this writing it is not clear that the programme will receive anything like the level of funding that was originally envisioned for it. Although a farm could conceivably get as much as $45,000 a year in support, on a per-acre basis the programme would pay no more than $22.25 an acre, with full implementation at the level of the third tier – considerably less than farmers have been receiving recently for leaving their land in corn. There is also concern about how green some of the practices the CSP will pay for really are, in part because the rules are still up in the air. Although it will probably on the whole encourage greener practices on the farms that are able to cope with its paperwork requirements, it is too soon to say if the CSP will significantly increase survival rates among sustainable farms.

Another factor that may depress sustainable farm survival rates comes, paradoxically, from a strength of PFI's get-along-but-don't-go-along approach. A farmer who has tried to seat his or her self on the tractor seat of the Big Ag monologue is also likely to be a farmer with a more unitary understanding of his or her self. The more dialogic self of a more dialogic knowledge cultivation, like PFI's, is a more multidimensional self, more accustomed to taking others into consideration and thus to envisioning what other selves might be like, including one's own self. While sustainable farmers may show no less commitment to being a farmer, to getting back on to that horse and to staying on it, they are also possibly more ready to consider other commitments when they find themselves slipping from the saddle once again. With a more open sense of who they are, they may be more ready to accept the outcomes of economic and other structural difficulties because they have come to see their senses of self as less dependent on those structures. They may be more ready to follow a path of self-reinvention, like one male PFI livestock and grain farmer who recently left farming to become a nurse.

But many of these points on the survival rates of sustainable farmers are at best informed conjecture. What we do know is that many PFI farms are prospering, perhaps as well as can be expected in such a high-risk, low-return endeavour as farming. We also know that other farmers are not exactly switching to sustainable practices with great alacrity. It is perhaps a steady trend, but it is still a slow one.

'I'm going to change the question a little bit about issues,' said Donna, moving on to one of our standard questions. 'What do you think are the most important issues facing farming today? The important issues facing rural families in America, even the world?'

'That's a tough one. I don't know where to start.' Brad paused to collect his thoughts. It was one of those open-ended questions that is so broad one hardly knows what to say at first.

'One issue revolves around the polarization that's taking place,' Brad said finally. 'Where out in rural America, maybe for all of America, for that matter, the extremes have the loudest voice. Extremes on both sides. In agriculture, it's the farmers that are getting bigger all the time. It's the corporate aspects of farming that are getting bigger, especially with hogs now. And then the other side is still those of us that are choosing to farm much differently, and trying to sell our food more directly to the consumer. And so you got that group versus the corporate type of farmer.'

Donna nodded and thought about saying something, but decided to stay quiet and let Brad's words tumble out more of their own accord. Meanwhile, Brad hesitated, perhaps to consider where he had got to, and perhaps to wonder if he felt right about calling his own side of farming as much of an 'extreme' as corporate farming. In any event, he clearly was concerned about monologic interactions between the two sides, each 'versus' the other, competing to be the 'loudest voice'.

'And then you got the rest,' he continued. 'Most of us are still caught in the middle yet, trying to figure out just where in the heck are we going.'

'Right,' said Donna supportively.

'It's just such a critical time, I think, for family farm agriculture. 'Cause I think we do have the opportunity to form networks and marketing groups and so forth, so that we can survive. But that's going to have to happen in the next five to ten years, or the opportunities will be gone. Then I think the other, the tremendous hurdle, is education of consumers and citizens in general about the value of farming the way we do.'

In other words, unless the dialogue of practical agriculture widens well beyond its current confines, the cultivation of broad agricultural sustainability is unlikely to come to pass anytime soon. As Brad noted, part of that broadening has to take place among farmers and others in the farming community, such as university researchers, government officials, bankers, agricultural implement dealers, agricultural implement makers, seed suppliers and commodity groups like the Iowa Corn Growers Association. Although Brad rightly worries that there is still much polarization here, much of the success of PFI has been exactly in its ability to invite the participation of others in the farming community into its conversations, into its knowledge cultivation, through the attractions of the group's dialogic approach. PFI has had the greatest impact on its local state university, Iowa State. It can be no accident that Iowa State in 1989 established the Leopold Center for Sustainable Agriculture, which is widely recognized as one of the nation's leading research and extension centres in sustainable agriculture. It can be no accident that in the fall of 2001 Iowa State University enrolled students in the nation's first graduate programme in sustainable agriculture.[8] PFI has also made connections with many of Iowa's traditional agricultural organizations, such as the Iowa Farm Bureau, with which it jointly hosts a series of field days every year to farms that are implementing sustainable practices. At its 2003 annual meeting, PFI hosted a session, led by a rural banker, on the role of bankers in sustainable agriculture. PFI understands what I earlier called the 'wonderful' quality of dialogue: that the inclusion of each additional voice in a dialogue encourages consideration of whomever else is missing, leading to the even greater widening of participation.

But Brad also pointed to another, equally important dimension of broadening the dialogue of practical agriculture: the 'tremendous hurdle', as he put it, of involving those who eat and use what farmers produce in the discussion over what agriculture has become and what it could instead be.

To overcome that hurdle, to encourage the broader relevance of agriculture, we will have to consider the arguments for why agriculture is irrelevant. I think we can divide these arguments into three general sorts, what we might call the *emptying* of agriculture, the *swamping* of agriculture, and the *obsolescence* of agriculture. All three of these arguments, I believe, are misleading.

The emptying of agriculture is probably the most familiar of the three, and it goes like this. Ours is now an urban world. Some 75 per cent of Americans live in urban areas, and 25 per cent in rural areas, the reverse of how things stood 100 years ago. True, worldwide, some 53 per cent of the human population remains rural.[9] Each year, however, the rural percentage drops, as more and more of the human more and more find their fortunes where the real fortunes seem always to be made: in cities. And those who remain in rural areas, particularly in the wealthy countries, are increasingly apt to take up pursuits similar to those of their city cousins – factory work, retail sales, government services. Moreover, rural people in rich countries and poor increasingly commute to urban areas for work. Hardly any rural people actually still farm, at least in the rich countries. In the US, farmers and farm workers are down to a couple of per cent of the workforce of the entire country.[10] Even in Iowa, where agriculture is a larger part of the economy than in any other state, farmers and farm workers account for only about 6 per cent of the employed workforce.[11]

The swamping of agriculture is a related point, although the direction of the argument runs the other way. It suggests that as people have left farms for the city, the forces of the city have taken over the farms. There is nothing special about agriculture anymore. It is an industry like any other, and a business like any other, too. In the words of the rural sociologist William Friedland, 'what is now called "agriculture" has become mostly sets of industrial processes physically located in the open air rather than under a roof.' Agriculture has been 'transformed beyond recognition,' Friedland says.[12] Increasingly, agriculture is a bad neighbour that local residents protest because of its pollution, just like a factory. And with the coming of 'pharming', in which what is grown is not food but bioengineered medicines, agriculture is no longer 'just like a factory'; it is a factory. There is no room here for any sentiment concerning community ties among rural residents, or between rural and urban residents. Agriculture is just a form of capitalism. Indeed, there is no reason even to call it agriculture anymore, suggests Friedland, as what we think that word means no longer exists.

Besides, as the agricultural economist Stephen C. Blank argues in *The End of Agriculture in the American Portfolio*, we don't really need agriculture anymore. Agriculture is obsolete. That's why there's no money in it, and that's why farmers are in such decline. Only a few consumers are willing to spend for their food what it would take to provide American farmers with a decent standard of living. 'In the simplest terms, the production of food and other agricultural products will disappear from the United States because it will become unprofitable to tie up resources in farming and ranching,' Blank argues. Although 'many of them will not believe it at the time,' he continues, many farmers 'will, in a number of ways, be better off after they make the difficult decision to leave agriculture voluntarily.' Good riddance to the high labour, high risk, high capital and low profit of farming. 'We need to strip away the romance and nostalgia surrounding agriculture and see it for what it is: a business,' Blank writes. 'We must learn to let go of farming and ranching.'[13] We won't starve. Farmers in developing countries, with their lower wages and lighter environmental regulations, will be able to export plenty of cheap food to us, Blank argues. And as long as there is plenty of edible goo for us to microwave up whenever we require it, why should we care?[14]

Now, it must be said that there is some truth to these three arguments for the irrelevance of agriculture in the US and other developed countries. More people do live in cities today, almost three-quarters of the developed world. The rural people that remain lead lives that are indeed much the same as those of urban folk, albeit with perhaps a bit more driving (or perhaps not, given the length of some urban commutes). We must admit that much of agriculture, if not most of it, hardly seems like farming anymore. To repeat the sociologist Paul Lasley's phrase, agriculture is increasingly just Ag-ag business, ag chemicals, ag machinery, and perhaps just plain agony for some, given the stress, the struggle, the loss of economic control, the loss of community, the loss of environment, the loss of culture. Also, the US has for many years been the world's largest food importer.[15] We are wealthy enough that we could probably easily import more, if need be.

For many, these trends are to be decried and resisted, lest we truly lose the real meaning of agriculture and the close interaction with communities natural and human that it affords and preserves. Indeed, this book might be read as such a decrying and resisting. And in a way it is. But in a way it isn't, for I believe that some of the concern to save agriculture is misplaced.[16] To decry and resist the 'emptying', 'swamping', or 'obsolescence' of agriculture is, in some measure, to accept the terms by which these three visions of the end of the agriculture frame our understandings. And to accept the terms of the end-of-agriculture debate, whether pro or con, is to accept an unhelpful presumption: that agriculture is something that farmers do.

As Wendell Berry has written, 'eating is an agricultural act'.[17] To eat is to shape the contours of farmland as effectively as any tractor. What we eat is what we grow. How we eat is how we grow. Why we eat is why we grow, and there are many reasons for eating in addition to attending to the necessary, if generally pleasurable, sustenance of our individual bodies. The pleasures and necessities of eating, as we understand them, may be as much about the connections it makes with other places and other lives as about the filling of the self.

Among those connections are connections to the rural places that yield the bulk of what we eat, and to the people who plant the seeds, tend the plants, and harvest the crop. In this sense, there has been no emptying of agriculture. There is just as large a percentage of people involved in agriculture as there has always been: all of us. There may be fewer farmers, but there are no fewer agriculturalists. Indeed, given the increase in the human population, there are substantially more.

Nor, in this sense, can we say that agriculture has been swamped by the forces of the city. There is nothing non-agricultural about urban living. Without agriculture, there would be no urban living, and indeed little human living of any kind. Agriculture is indeed in many ways much different from what it once was, but that's largely because urban life has become part of it, not because urban life has become a source of agriculture's demise.

Nor is agriculture obsolete. If we were to switch to importing all our food, that would not make agriculture any less a part of the American economic portfolio. We would still be eating, paying for it and shaping the lives of farmers and the land thereby. Those farmers and that land would just be that much further away, making our sense of connection to, and understanding of, eating as an agricultural act that much further away in our minds as well.

For while it is true, as long as we yet eat and live, that agriculture is not over, nor even close to it, it is also true that most of us no longer feel a part of its conversation.

In short, agriculture has largely become monologic. It speaks to us, not with us, and that goes for farmers as much as eaters. And it speaks to us with one logic: cheap food is all we should ask of agriculture. We don't want to pay more than we have to for our food, of course. This much is true. But the single-minded focus on producing vast quantities of food in order to feed the world at low cost keeps us from seeing the full connectedness of the agricultural conversation, the connectedness both between people and between people and the earth.

Among those connections are the implications of the cheap-food monologue for farmers, in both rich countries and poor. In the US, our agricultural subsidies, as we have seen, encourage ever-increasing production, which has the effect of driving down the prices farmers receive, which in turn leads them to try to stay on the treadmill and solve the farmer's problem by increasing their production even more. But although this process is often praised for keeping food costs down, it no longer has much impact on what eaters pay. Currently in the US, about 19 cents of every dollar spent on food goes back to farmers – about $123 billion of the $661 billion American consumers spend on food each year.[18] Decreasing that percentage even further would have little effect on food prices, as it is now such a minor fraction of the food dollar.[19] But it would almost certainly result in fewer farmers on the treadmill.

In fact, we are currently awash in food in the US, and in most other industrialized countries. The situation is so bad that, in order to prop up the prices farmers get, so that they don't all fold at once, we burn corn in our cars in the form of ethanol and we have an aggressive food export policy. In addition to being the world's biggest food importer, the US is the world's biggest food exporter. Which is supposed to help feed the world. But as I have discussed, most American agricultural products are too expensive for any but the relatively wealthy in other countries to purchase, the very people who are already eating pretty well. And in circumstances where American food – grain, primarily – does get to poor regions of the world, it tends to depress prices in those areas below what local farmers can make a living on, putting them out of work and making them even poorer. 'Feeding the world' with American grain is consequently often just a pretty slogan for commodity dumping.

Despite being awash in cheap food at home, there is nonetheless widespread hunger in the US. The US Department of Agriculture categorizes nearly 35 million Americans, including 13 million children, as 'food insecure' – approximately 12.5 per cent of the nation in 2002. Approximately 9.4 million live in households that the USDA classifies as 'hungry' – about 3 per cent of the nation.[20] This hunger persists despite the fact that Americans spend less of their income on food – about 11 per cent – than practically any other industrialized nation. But those are average figures. Poor people need to eat as much as rich people do, and although they cut costs and spend quite a bit less, they still spend a much higher proportion of their income on food. People making between $5000 and $10,000 a year spend about 33 per cent of their after-tax income on food.[21] Also, poor people in the US typically face higher food costs, as supermarkets today typically are located in suburban areas, away from where most poor people live.[22] The solution to hunger is not to increase food production in the US. Rather, it lies in reducing inequality here and abroad, in increasing food production within poor countries, and in protecting the environmental base of food production.

Also, most of us don't need more food. In the US there are perhaps greater health problems from overeating than from undereating, as the recent national discussion of obesity has underscored. We need better food. Given that we don't pay much for food to begin with; given that farmers don't get much of what we do pay; given that we currently spend our subsidies mainly to support high production, with relatively less attention to quality production – given all that, better food should be well within the nation's capabilities, without a significant increase in food costs, if any at all.

And we've been working on it, perhaps most notably through the recent growth in the production of organic food. Once found mainly in the form of tired-looking, expensive veggies in hippie co-ops, organic food is now big business. Some 39 per cent of US consumers report that they use organic products at least occasionally.[23] However, organic products are typically significantly more expensive and generally do not yet deliver on the promise of higher quality food with only a small price increase, or even a price decrease. Nor is organic production necessarily helping very many small farms to stay afloat, as organic increasingly becomes bought up into what the writer Michael Pollan has aptly termed the 'industrial-organic complex'.[24]

The point is, as Patricia Allen and Martin Kovach note, organic 'is simply not enough'.[25] Organic agriculture in itself does little to reconnect eaters with the agricultural conversation. In fact, it can be seen as largely a confirmation of their disconnection. What I mean here is that organic food retailing commonly trades on consumers' growing sense of unease with their disconnection from the agricultural conversation, and their consequent lack of trust in what they eat. Organic certification is narrowly based on production criteria. Buying organic food likely does support environmental protection and probably animal welfare, too, but in itself it has little to do with economic justice and bringing people back into the agricultural conversation. The focus of the organic label and its associated inspection system is on individual consumer health in an untrusting world – on what the sociologist Melanie Dupuis has termed 'not in my body' sensibilities – more than reconnecting eaters with a dialogic, practical agriculture.[26]

We have become used to seeing agriculture as a realm out there in the beyond that we have left behind, physically and culturally. This beyond and behind notion of agriculture envisions it as a space, something that we enter when we leave, or perhaps escape, the sprawling city and the artifice and ambition we sense there. Agriculture now feels distant, something that we rarely see and that little impinges on our daily activities. Agriculture feels like a product line – shall I have the Cortlands or the Fujis or the Granny Smiths? – not a relationship to other humans and the earth. That feeling of the product line is part of the feeling of distance, for disconnection is distance.

So why not bring agriculture back home, to everyone's homes? The pleasures of this connection are what Jack Kloppenburg, John Hendrickson and Steve Stevenson mean when they speak of 'foodshed' thinking. The increasingly globalized food system of today encourages a sense of placeless food. Sure, we might know that in North America oranges come from Florida in the winter and from Brazil in the summer, and it may even say so on the signs in the supermarket produce aisle. But here place is used mainly as a sort of brand. We get little sense of the lives of those who raised, sorted and shipped these oranges. We get little sense of the environmental implications of their methods. They're just oranges, some cheaper, some more expensive; some sweeter, some a bit more dried out. But thinking of the food we eat as flows in a foodshed, like flows of water in a watershed, gives direction to the movement of food, and thus an origin to food in specific places and in the specific lives lived there. Foodshed thinking makes all food homemade, for it connects us to the home places of what we eat.

Foodshed thinking also teaches where we ourselves are. 'The foodshed is a continuous reminder that we are standing in a particular place; not anywhere, but here,' write Kloppenburg, Hendrickson and Stevenson.[27] It leads to what Thomas Lyson has called 'civic agriculture' – a 'locally-based agricultural and food production system that is tightly linked to a community's social and economic development', in Lyson's words.[28] And it is leading to it with a will. Communities across the world, especially in those places where food had become the most placeless, the most monological, are returning to local foods, and the dialogic connections to people and environment that is their sweetest taste. In the United States, we have seen an enormous growth of farmers' markets, farm stands, pick-your-own, community-supported agriculture (CSA) projects, community gardens, community farms, community kitchens, institutional buying of local products, and small-scale food processing. For example, between 1994 and 2002 the number of farmers' markets around the country rose from 1755 to more than 3100, a 77 per cent increase.[29] There are now more than a thousand CSA, or subscription, farms in the United States, with more than a hundred thousand member households.[30] Although they are sometimes threatened by development pressures, the growth of community gardens and community farms has been bringing agriculture right back into the city, making the eaters the growers.[31] People are coming to savour the taste of place and the enjoyments of eating locally, eating seasonally, and eating in ways that support local farmers and local communities.

The point of local agriculture is not that North Americans need to give up tea, coffee and bananas. The point is that, in a food system in which what we eat may come from thousands of miles away and where the typical food item is handled 33 times from field to supermarket shelf, there is abundant room to cut way back on the 'middlemen' so as to give a greater share of the food dollar to farmers, while giving eaters healthier, tastier, more environmentally friendly, community-supporting and quite possibly even cheaper food.[32] And everyone gains a sense of connection, of dialogue between grower and eater.

PFI has been among those groups that have in recent years worked hard to provide that connection and dialogue. Through its Field to Family project, PFI has worked to combine issues of equity and sustainability with local eating and local sourcing of food. PFI instituted a 'healthy food voucher' programme that enabled low-income families to participate in the CSA project the group helps coordinate. PFI has organized local institutions to use local sources of food, such as the campus conference center at Iowa State, which now provides an 'all-Iowa meal' option for organizations that use the facility. PFI regularly conducts cooking classes and nutrition classes so that eaters can regain the skills of healthy and efficient home food preparation. PFI started up a farmers' market in Ames, the city where Iowa State is located and where PFI's own offices are. PFI started an annual youth summer camp centred on sustainable agriculture and sustainable food, and began a gardening and nutrition programme with the Ames Boys and Girls Club.

But perhaps the greatest effort that PFI has made to connect farmers and eaters came in 2002, when its members voted to allow non-farmers to become full voting members of the group. The group still asks people to state on their membership application whether they gain 'a significant part' of their income 'directly from farming in Iowa'. And only those who check this box can serve on the group's board. So it is still at heart a farmers' organization. But anyone can join and vote, and half of the group's roughly 700 members are eaters, not farmers, who have taken up this invitation to engage in the dialogue of what a practical agriculture could look like – this invitation to find a place in the wordshed of the foodshed.

The broad sense of connection underlying foodshed thinking allows us to dispense with another unhelpful presumption about agriculture: that its purpose is only to grow food (and fibre and, I suppose, medicine now). We do want agriculture to grow food for us (and fibre and, perhaps, medicine). But growing food is only one dimension of what I would argue is the purpose of agriculture: *cultivation* – the care and tending of creation, human and non-human, social and ecological. Here I mean cultivation in a way different from but related to how I have used it earlier in this book. Here I mean it not as the relationship between who we are and what we know, as the culture of identity and the identity of culture. I mean cultivation as the culture of the earth, as the husbandry and wifery of life, as farming for us all.

Cultivation, then, is a task not only for those people we have long regarded as the agriculturalists. It is a task not only for farmers. It is a task for everyone. I worry, though, that the image of the farm tends to guide our thinking back to a sense of agriculture as the beyond we left behind. There couldn't be a farm in a city, right? A city couldn't itself be a farm, could it? There is something jarring to the pattern of our imagination here.

Thus I suggest, along with Harriet Friedmann, that we imagine the dominant metaphor of agriculture as that of the garden, the *garden* writ large, for a garden is something that I believe we are more used to understanding as potentially everywhere, in city and countryside alike.[33] We are more used to identifying ourselves as potentially all gardeners than as potentially all farmers. Moreover, there is an intimacy and care associated with gardening, an intimacy and care that Big Ag has, to a

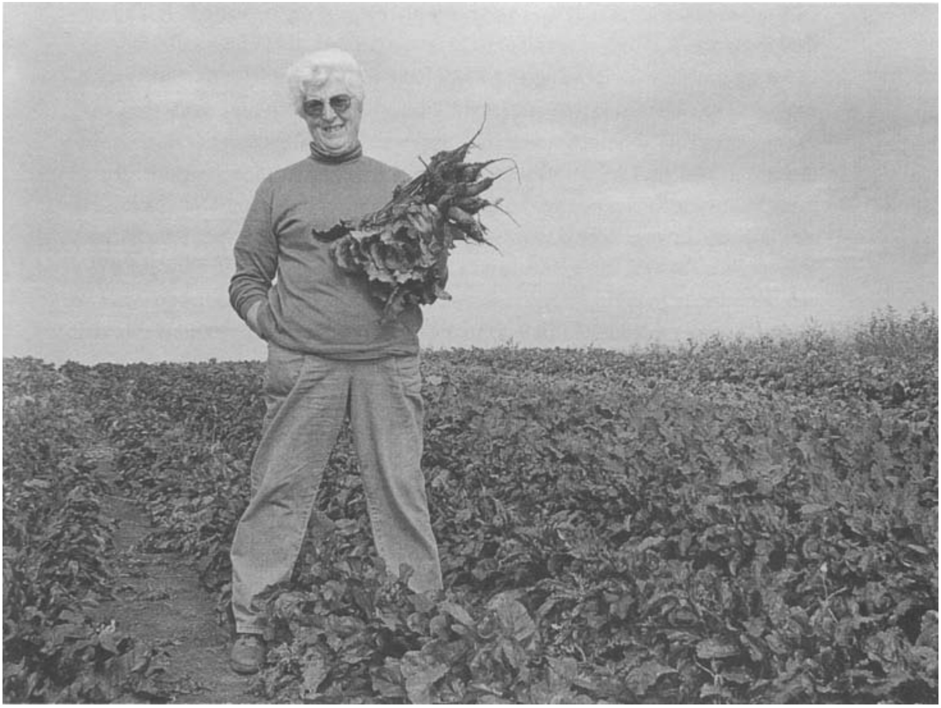

Figure 20.2 *Virginia Moser, PFI member, at the CSA farm she operates with her husband, Marion Moser, 1999*

large extent, driven out of our image of farming. And indeed most farms today do not feel remotely like gardens. Nor do most of our towns and cities, our schools and neighbourhoods, our workplaces and our public life, at least not much of the time. These too are increasingly a form of Big Ag, farming us all, not farming for us all.

So let us put the culture back in agriculture of all forms and in all places. Let cultivation of what Friedmann has termed the 'gardens of Gaia' become our understanding of what the rural is and what farming should be – of what we sometimes succeed in and so often fail to attain in actual social and ecological life in both country and city.[34] To speak of agriculture, then, in this ideal sense, is to consider the degree to which a state of mind and action brings out, or fails to bring out, the gardener's capacity of care for creation.

Which brings us back to dialogue and sustainability. It is something of a romance, I freely confess, to consider agriculture as cultivation in this largest sense, as care of the earth. But it is a romance that allows us to appreciate how the current structures of production so overwhelm our better intentions for the cultivation of the garden. It is a romance with material consequences. It is a practical romance. But only if we all engage in the conversation of agriculture.

For we probably do not all agree about what it means to care for the earth and its ecological and social creation. And that is fine. More than that: it is great – as long as we engage our differences and take responsibility for response ability, for difference is creativity's own unfinalizable wellspring. By coming to imagine agriculture as here and now, wherever we are, and not beyond and behind, we ask for and welcome that engagement. Eaters, growers, purveyors, teachers, builders, doctors, lawyers, bus drivers, factory workers, scientists, even realtors and regulators: we are all potentially agriculturalists in the sense of the gardening of creation. It depends upon our state of mind and action, upon how we contribute to this task that is, thankfully, larger than any of us.

This, I believe, is the practical message of Practical Farmers of Iowa: that cultivation in the agricultural sense depends upon an approach to cultivation in the social sense that embraces the creativity of difference, openness and the unfinalizable. A dialogic, practical agriculture requires that we all consider agriculture a central feature of everyone's lives, worthy of everyone's care and careful attention. A dialogic, practical agriculture requires that we sustain the broadest possible conversation about agriculture. For what Iowa's practical farmers are really trying to farm is democracy, the democracy of the people's good earth. The same is true of practical farmers everywhere. They are all guided by a common insight: that farming for us all, in every field of human endeavour, is only possible when there is farming by us all.

Acknowledgements

As I sit down to write these acknowledgements, the autumnal equinox fast approaches and the harvest is on in the Midwest. It's a time for finishing up, for gathering together, for putting things away, for reflecting on the season past. As day and night near equality, it's a time for assessing the balance of things. And it's a time for giving thanks.

Harvest and the equinox thus seems to me a very good time to write the acknowledgments for a book long in cultivation, perhaps especially for a book about farming. When the crop is full ripe (or as ripe as it's going to get), it needs to be gathered together. And so it is with the crop of this book. It is time to finish up. It is time to reflect on the season past and to give thanks for those who have contributed so much to its fruits.

A common myth – there can be no other word for it – is that the real farmer farms alone, toiling single-handedly against the elements, and that every farm has only one farmer. He (in the myth it almost always is a he) is the farmer. The others are farm workers, farmhands, farm wives, farm kids. The members of Practical Farmers of Iowa and other sustainable agriculture groups, as this chapter describes, are struggling to overcome this singular understanding of the authorship of a farm, as part of their efforts to create a more dialogic, and thus more practical, agriculture. We need also to struggle against the parallel myth of the single authorship of a book. No author truly works alone. No book truly has just one author.

This is particularly true of a book such as this one. Central to whatever fruit this book can be said to offer are the participatory methods with which the underlying research was conducted. Without Donna Bauer and Sue Jarnagin of Practical Farmers of Iowa and their on-the-ground insights, and without Greg Peter's master's thesis work, this book would have been not only less informed, less intelligent, less relevant, less valid and reliable a witness of the conditions of farming today – to the extent it has any of these good qualities – it would have been a whole lot less fun. To them I owe the biggest thanks.

Notes

1 Dick describes this experience as follows in Thompson, Thompson and Thompson (2002, p1–3): 'Several years ago while cleaning out a hog waterer, Dick heard a voice that said, "Get along but don't go along." There was no other person around at the time. This concept is what we are supposed to do. We don't have to convict or convince anybody, just share when asked. This makes the yoke easier and the burden lighter. This policy has left the door open to go to many land grant universities in the United States and overseas during the last few years.'

2 This is also in keeping with what I have elsewhere termed the 'dialogue of solidarities' (Bell, 1998).

3 Three members I asked said they thought survival rates of sustainable and conventional farms were about the same. A couple thought the rate was slightly higher for sustainable farms.

4 Environmental Working Group (2002) figures, divided by the 96,000 farms the US Agricultural Statistics Service recorded for Iowa in 1999. Anthan (2001) reports considerably higher subsidy figures, but the Environmental Working Group is more reliable.

5 Environmental Working Group (2002).

6 I looked up their subsidy on the internet, courtesy of the Environmental Working Group, www.ewg.org, which has usefully posted the subsidy figures for every farmer in the US.

7 See, for example, the website of the Minnesota Project, a nonprofit Minnesota environmental group, www.mnproject.org/csp/.

8 I make this observation with some caution, as I was myself involved in establishing this programme. Thus readers should take into consideration that I may have some personal interest in promoting its significance.

9 Figure for 1999 (United Nations Population Fund, 1999).

10 The precise figure of Iowa farms that raise livestock, as of the 1997 agricultural census, was 57 per cent (National Agricultural Statistics Service, 1999, Table 2). However, the number is dropping fast. Many thousands of hog farmers gave up during the steep price dip during the winter of 1998–1999, and thus the percentage of Iowa farms with livestock now is probably below 50 per cent.

11 Based on dividing the number of farms in Iowa in 2002 (92,500, according to the Iowa Office of the National Agricultural Statistics Service, 2003) by the size of the employed labour force in the state (1,560,300, according to Iowa Workforce Development, 2003), one gets a higher figure than the slightly less than 5 per cent I earlier derived from Otto, Swenson and Immerman (1997), to which I have added a per cent or so for farm workers.

12 Friedland (2002, pp352, 368).

13 Blank (1998, pp1, 3, 193, 195).

14 I'm adapting a line here from the Iowa State University agricultural economist Mike Duffy (personal communication), who certainly is no fan of food as edible goo.

15 It is also the world's largest food exporter, a point that Blank does not consider closely.

16 For examples of the Jeffersonian view that I wish to sidestep, see Comstock (1986).

List of Acronyms and Abbreviations

ABE/GED	Adult Basic Education/General Education Development
AAD	Agro-ecosystem Analysis and Development
ACORN	Association of Community Organizations for Reform Now
APCSA	Ecuadorian Association for the Protection of Crops and Animal Health (now Crop Life Ecuador)
BMDC	Blue Mound Development Corporation
BMSC	Blue Mound Store Corporation
BPH	brown planthopper (of rice)
BSE	bovine spongiform encephalopathy
CAFO	concentrated animal feeding operation
CAP	Common Agricultural Policy (EC)
CAS	Chinese Academy of Sciences
CAST	Council for Agricultural Science and Technology
CDC	Centers for Disease Control and Prevention
CDC	Community Development Corporation
CGIAR	Consultative Group on International Agricultural Research
CIAT	Cantro Internacional de Agricultura Tropical
CIP	International Potato Center
CJD	Creutzfeld–Jakob Disease
CRP	Conservation Reserve Program
EA	Environment Agency (UK)
EEC	European Economic Commission
ERS	Economic Research Service
EU-FAO IPM	European Union-Food and Agriculture Organisation Integrated Pest Management
EU	European Union
FAO	Food and Agriculture Organization (UN)
FEMA	Federal Emergency Management Agency
FFS	Farmer Field School
FIC	farmer innovation circles
FSIS	Food Safety and Inspection Service
HACCP	Hazard Analysis and Critical Control Point
HCN	household communication networks
HIC	household innovation capacity
ICRISAT	International Crops Research Institute for the Semi-Arid Tropics

IESWTR	Interim Enhanced Surface Water Treatment Rule
INIAP	National Institute of Agricultural Research from Ecuador
IPM	Integrated Pest Management
IPPM	Integrated Production and Pest Management
IRRI	International Rice Research Institute
JFM	joint forest management
KFTC	Kentuckians for the Commonwealth
LDC	less developed country
LSD	least significant difference
LSP	Land Stewardship Project
MRL	maximum residue levels
NAO	National Audit Office
NGO	non-governmental organization
NRM	natural resource management
OP	organophosphate
OPM	organic pest management
OTA	Office of Technology Assessment
PPE	personal protective equipment
RCCI	Rural Community College Initiative
RHTs	resource and habitat taboos
S&S	signs and symptoms
SDWA	Safe Drinking Water Act
SESA	Ecuadorian Plant and Animal Health Service
SOCM	Save Our Cumberland Mountains
SRI	System of Rice Intensification
SUP	safe use of pesticides
TOA	Trade-off Analysis
ToF	Training of Facilitators
UN	United Nations
USACE	US Army Corps of Engineers
USDA	US Department of Agriculture
WED	Women, Environment and Development
WHO	World Health Organization
WTAC	willingness to accept compensation
WTP	willingness to pay

Editorial Introduction to Volume II

Jules Pretty

The Real Costs

When we buy or bake our daily bread, do we ever wonder about how much it really costs? We like it when our food is cheap, and complain when prices rise. Indeed, riots over food prices date back at least to Roman times. Governments have long since intervened to keep food cheap in the shops, and tell consumers that policies designed to do exactly this are succeeding. In most industrialized countries, the proportion of the average household budget spent on food has been declining in recent decades. Food is getting cheaper relative to other goods, and many believe that this must benefit everyone as all need to eat food. Food is not cheap. It only appears cheap in the shop because consumers are not encouraged to think of the hidden costs of damage caused to the environment and human health by certain systems of agricultural production.

Thus consumers actually pay three times for their food. Once at the till in the shop, a second time through taxes that are used to subsidize farmers or support agricultural development, and a third time to clean up the environmental and health side effects. Food looks cheap because these costs are only accounted for elsewhere in the economy. The real costs are thus not internalized in prices. On the cheapness of food, Donald Worster recognized this in his *The Wealth of Nature* (1994): 'the farm experts merely assume, on the basis of marketplace behaviour, that the public wants cheapness above all else. Cheapness, of course, is supposed to require abundance, and abundance is supposed to come from greater economies of scale, more concentrated economic organisation, and more industrialised methods. The entire basis for that assumption collapses if the marketplace is a poor or imperfect reflector of what people want.'

This is not to say that prices in the shop should necessarily rise, as this would penalize the poor over the wealthy. Using taxes to raise money to support agricultural development is also potentially progressive, as the rich pay proportionally more in taxes, and the poor, who spend proportionally more of their budget on food, benefit if prices stay low. But this idea of fairness falters when set against the massive distortions brought about by modern agricultural systems that additionally impose large environmental and health costs throughout economies. Other people and institutions pay for these costs, and this is both unfair and inefficient. If it were possible to add up the real costs of producing food, we would find that modern industrialized systems of production perform poorly in comparison with sustainable systems. This is because we permit cost-shifting – the costs of ill health, lost biodiversity and water pollution are transferred away from farmers, and so not paid by those producing the food nor included in the price of the products sold. Until recently, though, we have lacked the methods to put a price on these side effects.

When we conceive of agriculture as more than simply a food factory, indeed as a multifunctional activity with many side effects, then the idea that farmers do only one thing must change. Of course, it was not always like this. It is modern agriculture that has brought a narrow view of farming. The rural environment suffers as environmental services are affected, the food we eat is as likely to do as much harm as good, and we still think food is cheap. The external costs and benefits of agriculture raise important policy questions. In particular, should farmers receive public support for the public benefits (environmental and health services) they produce in addition to food? Should those that pollute have to pay for restoring the environment and human health? These two principles are called 'the provider gets' and 'the polluter pays', and they are important for both industrialized and developing countries. Three categories of policy instruments are available: advisory and institutional measures, regulatory and legal measures, and economic instruments. Effective pollution control and the supply of desired public goods requires a mix of all three approaches, together with integration across sectors.

A range of policy reforms could do much to internalize some of these costs and benefits in prices. In practice, as no single solution is likely to suffice, the key issue rests on how policy makers choose an appropriate mix of solutions, how these are integrated, and how farmers, consumers and other stakeholders are involved in the process of reform itself. Attention will therefore need to be paid to the social and institutional processes that both encourage farmers to work and learn together, and result in integrated cross-sectoral partnerships. Policy integration is vital, yet most policies seeking to link agriculture with more environmentally-sensitive management are still highly fragmented.

One problem is that many environmental policies have tended only to green the edges of farming. Thus an essentially modernist agriculture remains much as it ever was, but is now light green. Many non-crop habitats have been improved, including hedges, woodlands and wetlands. But the food is still largely produced in a conventional manner. The bigger challenge is to find ways of substantially greening the middle of farming – in the field as well as around the edges. A thriving and sustainable agriculture requires both integrated action by farmers and communities, and integrated action by policy makers and planners. This implies both horizontal integration with better linkages between sectors, and vertical integration with better linkages from the micro to the macro level. Most policy initiatives remain piecemeal, affecting only a small part of farmers' practices, and so do not yet lead to substantial shifts towards sustainability.

Part 1: Agricultural Harm to the Environment

The first paper is the iconic opening chapter to Rachel Carson's *Silent Spring*. It is just two pages in length, and is entitled *A Fable for Tomorrow*. Written in the early 1960s, and later to influence generations of scientists, consumers and policy makers, it is a story of modern society and the consequences of environmental and social decay. It is told as a fable, which is clever. It does not seek to be analytical or specific to one set of circumstances. The fable generalizes, and so must be inaccurate about certain places. But its very nature captures attention, and shows how Carson was so influential. It starts, 'there was once a town in the heart of America', and describes its checkerboard of prosperous farms, with oak and maple and birch, and foxes barking in the hills. Fish swum in the streams that flowed clear and cold out of the hills. But 'then a strange blight crept over the area, and everything began to change'. Some evil spirit settled on the community, and no one knew why. There was a strange stillness. The birds were silent: 'it was a spring without voices'. The tragedy is, of course, that 'the people had done it themselves' with their adoption of modern agricultural methods.

In the second article, an excerpt from the 2002 book, *Agri-Culture*, Jules Pretty indicates that the real costs of food are much higher than the price paid in the shop. Environmental externalities and the diversion of tax revenue to subsidize agriculture contribute to the real cost. Agriculture, like any economic sector, has both negative and positive side effects, and it is the movement towards a more multifunctional view of agriculture that could result in a better understanding of what contributes to agricultural sustainability. This paper summarizes the first study of the full costs of a national agricultural sector. In the UK, these amounted to some £1.5 billion per year during the 1990s. These external costs are alarming – and should call into question what is meant by efficiency. Increased sustainability in agricultural systems can only happen if these external costs are substantially reduced.

In the third paper, Erin Tegtmeier and Michael Duffy analyse the full cost of modern agricultural production in the US. These are of the order of $5.6–16.9 billion per year (in 2002 $), arising from damage to water resources, soils, air, wildlife and biodiversity, and harm to human health. Additional annual costs of $3.7 billion arise from agency costs associated with programmes to address these problems or encourage a transition towards more sustainable systems. Following various partial studies published in the 1990s, this was the first study of the costs of the whole of the agricultural sector in the US. As the authors indicate, 'many in the US pride themselves on our cheap food. But this study demonstrates that consumers pay for food well beyond the grocery store.'

The fourth article by Steve Sherwood and co-authors is a chapter drawn from the 2005 book, *The Pesticide Detox*. It focuses on pesticide use and its effects in the highland region of Carchi in the northern Andes. Farmers use a wide range of pesticides, both hazardous and benign, and although local and international businesses indicate that highly toxic products can be used safely, the evidence from the ground is different. This study found that poisonings in Carchi are amongst the highest recorded in the world – an annual rate of 171 per 100,000 population for morbidity, and 21 per 100,000 for mortalities. Pesticides were found on family clothing, on food and in children's bedding. To illustrate these pathways to local people, the researchers added fluorescent dyes to pesticides, and then used UV lights to show their presence. The challenge, now, is to develop new ways of learning about pests and diseases in such rural communities, as well as to develop agricultural practices that reduce dependency on those pesticides that are harmful to humans and the environment.

Although some pesticides are known to be harmful to people, there are surprisingly few empirical studies that analyse their effects. At the global level, the World Health Organization (WHO) can only estimate very broadly the number of farmers, families and consumers who might be affected. This paper by Francesca Mancini and colleagues makes an important contribution to knowledge by conducting a season long assessment of acute pesticide poisoning in three villages of Andhra Pradesh in India. An average of 20 pesticide applications are made per season on cotton. Some 323 adverse events were reported amongst both men (who apply the pesticides in the fields) and women (who mix products and refill spray tanks). More than 80 per cent of the events were associated with signs of mild to severe poisoning; and 10 per cent of pesticide application sessions caused three or more neurotoxic symptoms associated with organophosphate products. Although 6 per cent of the spray sessions caused severe neurotoxic effects, no farmers or workers sought medical care. Low income, marginal farmers were more often subjected to severe poisoning than landlords. The paper concludes by indicating that Integrated Pest Management (IPM) methods that reduce the health burden on local people should be pursued.

Part 2: Agroecology and Sustainability

Agroecosystems are ecological systems modified by humans to produce food, fibre or other agricultural products. This classic paper by Gordon Conway discusses the boundaries and components of agroecosystems, which can be regarded as true cybernetic systems whose goal is increased social value. Agroecosystems exist in a hierarchy from plant-environment to field, farming system, watershed and so on, and systems theory indicates that the behaviour of higher level systems cannot readily be discovered from a study of lower systems, and vice versa. This paper makes a significant contribution by indicating that agroecosystems have four key properties: productivity, stability, sustainability and equitability. Agricultural development inevitably involves making trade-offs between these properties. The four properties are linked to one another, both within an agroecosystem and between agroecosystems at different levels in a hierarchy. The trade-offs can be seen clearly in the history of agriculture, and this paper describes four key examples: the origins of agriculture, involving the domestication of wild cereals to increase stability but not necessarily, at first, to increase productivity; manorial agriculture of the British Middle Ages; modern western agriculture; and the green revolution in Indonesia. The paper ends by suggesting the need for practical analytical tools and development packages that emphasise multidisciplinary approaches, such as agroecosystem analysis.

The second article by Carl Folke and colleagues analyses the characteristics of social-ecological systems. They seek to provide a rich understanding of not just human–environment interactions but of how the world we live in actually works and the implications it has for current policies and governance. The chapter emphasizes that the social landscape should be approached as carefully as the ecological in order to clarify features that contribute to the resilience of social-ecological systems. These include vision, leadership and trust; enabling legislation that creates social space for ecosystem management; funds for responding to environmental change and for remedial action; capacity for monitoring and responding to environmental feedback; information flow through social networks; the combination of various sources of information and knowledge; sense-making and arenas of collaborative learning for ecosystem management. Their work illustrates that the interplay between individuals (e.g. leadership, teams, actor groups), the emergence of nested organizational structures, institutional dynamics, and power relations tied together in dynamic social networks are examples of features that seem critical in adaptive governance that allows for ecosystem management and for responding to environmental feedback across scales. They conclude that the existence of transformative capacity is essential in order to create social-ecological systems with the capability to manage ecosystems sustainably for human well-being. Adaptive capacity will be needed to strengthen and sustain such systems in the face of external drivers and events.

The third article by Stephen Gliessman is an overview of agroecological approaches to the management of agricultural systems. As he indicates, 'discussions about sustainable agriculture must go beyond what happens within the fences of any individual farm'. It is the wider environmental, economic and social interactions that are critical. A practising farmer as well distinguished academic, Gliessman draws on a wide range of experience to set out an agroecological perspective to the flows of energy and nutrients in agroecosystems, and identifies the population regulating mechanisms and potential for developing dynamic equilibira. The paper includes a table that summarizes the guiding principles for a process of design of and conversion to sustainable agricultural systems. Comparisons are made between traditional, conventional (or modern) and sustainable systems. This question of redesign is critical if different patterns of agricultural and environmental management are to emerge, patterns that are able to produce both food and important environmental services.

In the fourth article, Kevin Gallagher and co-authors describe the ecological and social basis for IPM in rice agroecosystems in Asia. The chapter, drawn from the book *The Pesticide Detox*, first sets out the specific ecological basis of rice fields, and why continued pesticide applications have not resulted in cheap and effective pest control. Pesticides may kill pests in the short term, but they also eliminate natural enemies that exert good ecological control over pests. The idea behind IPM is to put technologies into the hands of farmers and communities, so that they learn to farm with low to zero use of pesticides, yet also do not suffer pest losses. Many tens of thousands of farmer field schools have been held throughout Asia, and these have been highly effective at increasing farmers' own capabilities and knowledge for ecological management of rice fields. Many countries are now reporting large reductions in pesticide use. In Vietnam, two million farmers have cut pesticide usage from more than three sprays to one per season; in Sri Lanka, 55,000 farmers have reduced usage from three to a half per season; and in Indonesia, one million farmers have cut usage from three sprays to one per season. In no case has reduced pesticide use led to lower rice yields. Amongst these are reports that many farmers are now able to grow rice entirely without pesticides: a quarter of field school trained farmers in Indonesia, a fifth to a third in the Mekong Delta of Vietnam, and three-quarters in parts of the Philippines.

In the final article, Dana Jackson of the Land Stewardship Project describes the way that farms can be developed as part of natural habitats. As she says, 'it's hard to imagine what it must have looked like when Europeans first settled the midwest, when it was a wilderness with prairie, forest, clean streams and herds of buffalo. Too quickly it became dominated by agriculture.' The remaining wildlands are preserved and protected in parks and reserves, but that leaves the great majority of land directly shaped by the business of food production. Jackson introduces an alternative vision for this agriculture that is inspired by Aldo Leopold, and which indicates that farming and natural areas should be interspersed, not separated. There are many benefits of thinking differently – the benefits of biodiversity for farming itself, and the effects of more sustainable farming on biodiversity. We must teach, as Jackson says, that 'the land is one organism'.

Part 3: Communities and Social Capital

In the first article, Mary Mellor sets out the case for a deep materialist perspective on feminism and environmental ethics. Unlike some other writers, she does not claim that women have a superior vision, or higher moral authority, but indicates that an ethics that does not take account of the gendered nature of society is doomed to failure, as it will not confront the structure of society and how that structure impacts on the material relationship between humanity and nature. Mellor helpfully summarizes a number of traditions, from feminism and environmental ethics, to eco-feminism, materialist feminism, mediation in human–nature relations, deep materialism, ecological holism, and immanent realism. She argues 'that the politics of human–nature relations is critical. There is no natural balance in nature, and so any form of sustainable connectedness would need to be created through human reason and political action.' The problem, of course, is how political change can occur. Should it be driven from the top, or does political agency need to come from people and groups who are exploited, marginalized and excluded by the existing social and ecological structures? Mellow indicates that 'building coalitions and coordinated political action are essential'. The basis for this position is that knowledge about the natural world will always be partial, and so 'awareness of the radical uncertainty of human immanence should be the starting point of all other knowledge'. Humanity is part of a dynamic iterative ecological process where the whole is always more than the sum of the parts.

It is increasingly well-established that social capital is an important factor in building and maintaining collective action, which is in turn fundamental to substantial and long-term changes in natural resource management. Analysis of causal relationships among improved resource management and collective action has hitherto centred on the existence or creation of appropriate institutional and property arrangements, but there is an emerging recognition that relations of trust and common values are important to collective action. In the second paper, Westerman et al contribute to an improved understanding of the gender aspects of social capital manifested in groups for natural resource management. They investigate how gender differentiated social groups differ in their activities and outcomes for natural resource management. Men's, mixed and women's groups were analysed in 46 rural programmes in 20 countries of Latin America, Africa and Asia. Significant gender differences were found in relation to group maturity and natural resource management achievements and approaches as well as important differences in experiences of collaboration and capacity to manage conflict. Overall they found that collaboration, solidarity and conflict resolution all increase as women's presence in groups increases. In addition, norms of reciprocity are more likely to operate in groups where women are present. Similarly, capacity for self-sustaining collective action increased with women's presence and was significantly higher in the women's groups. The results demonstrate the importance of gender analysis for collective natural resource management and particularly the role of women for collaboration in and the sustainability of natural resource management groups.

In the third article, Jules Pretty sets out the importance of social capital in the collective management of natural resources. The term social capital captures the idea that social bonds and norms are important for people and communities. It emerged as a term following detailed analyses of the effects of social cohesion on regional incomes, civil society and life expectancy. As social capital lowers the transaction costs of working together, it facilitates cooperation. People have the confidence to invest in collective activities, knowing that others will also do so. They are also less likely to engage in unfettered private actions with negative outcomes, such as resource degradation. Four features are important: relations of trust; reciprocity and exchanges; common rules, norms and sanctions; connectedness in networks and groups. Collective resource management programmes that seek to build trust, develop new norms and help form groups have become increasingly common, and are variously described by the terms community-, participatory-, joint-, decentralized-, and co-management. They have been effective in several sectors, including watershed, forest, irrigation, pest, wildlife, fishery, farmers' research, and micro-finance management. Since the early 1990s, some 400,000–500,000 new local groups were established in varying environmental and social contexts, mostly evolving to be of similar small size, typically with 20–30 active members, putting total involvement at some 8–15 million households. The majority show the inclusive characteristics identified as vital for improving community well-being, and evaluations have confirmed that there are positive ecological and economic outcomes, including for watersheds, forests and pest management.

A classic study conducted in 1946 by Walter Goldschmidt showed what happens when the social structure in the countryside changes during modernization. He studied the two rural Californian communities of Arvin and Dinuba in the San Joaquin Valley. These were matched for climate, value of agricultural sales, enterprises, reliance on irrigation, and distance from urban areas. The differences were in farm scale: Dinuba was characterized by small family farms and Arvin by large, commercialized farms. There were striking differences between the two communities. In Dinuba, there was a better quality of life, superior public services and facilities, more parks, more shops and retail trade, more diverse businesses, twice the number of organizations for civic improvement and social recreation, and better participation by the public. A study of the same communities in the late 1970s reaffirmed these findings. Recent years have brought severe financial crises for family farmers, as they were squeezed by debt and low prices. Many thousands lost their businesses. Others, though, did not see this as a problem, but as desirable, as small farmers were widely taken to be economically inefficient. But their loss has been a severe loss to rural society. Linda Lobao's paper shows the importance of the locality that Goldschmidt illustrated. The changing structure of farming has brought about a decline in rural population, increased poverty and income inequality, lower numbers of community services, less democratic participation, decreased retail trade, environmental pollution and greater unemployment. The decline of family farming does not just harm farmers. It hurts the quality of life in the whole of society. Corporate farms are good for productivity, but not much else: 'this type of farming is very limited in what it can do for a community … we need farms that will be viable in the future, correspond to local needs and remain wedded to the community'.

The final paper of this section by Bin Wu and Jules Pretty analyses social connectedness in a marginal rural region of China. Despite remarkable recent achievements, rural poverty still presents significant challenges in China. Poverty is particularly endemic in marginal areas characterized by problems of both poor asset stock (natural, physical and human capital) and the scarcity of capital inflows (e.g. in terms of finance, technology, information and talent). If there is to be a breakthrough for rural development in these marginal areas, then agricultural innovation is widely viewed as a necessary condition. Yet technological innovation is constrained by the difficulties that formal agricultural extension finds in reaching remote and inaccessible areas. This lack of communication and interaction between farmers and agricultural professionals constrains the fit between the supply of new technologies and the pressing needs of the rural poor. Hitherto, most attention has been paid to improvement of development assistance and agricultural extension, rather than assessing the development potential of marginal communities themselves. These are dynamic and diverse, with great potential for innovation in both technologies and self-organization. This paper explores the implications of farmer innovation and local self-organization for government and agricultural professionals. The focus is on rural communities of north Shaanxi in China and the phenomenon of 'farmer innovation circles'. These are informal social systems used by the rural poor for their own technology development and cooperation. The paper explains the theoretical background and analytical framework, then summarizes the features of Zhidan County and methodology used. The distribution of household innovative capacity is then linked to wider innovation circles and household incomes. Overall, the paper shows how innovative capacity is accumulated, and concludes with reflections on the development and policy implications.

Part 4: Ecological Restoration and Design

In the first article of this section, David Orr sets out the components and principles of ecological design and education. Ecological designers know one big thing – everything is hitched to everything else. This suggests a need for a blending of nature with human-crafted space, a bringing together of arts, crafts, science and architecture. But this is easy to say, and hard to achieve. We will need to spend more time thinking about how we see the world, and how we learn from it. A number of key principles are set out for a new type of design that recalibrates education with ecology. Nature is not something to be mastered, but a potential tutor and mentor for human actions. But ecological design is deeper than mimicry. It should encourage us to ask what will nature permit us to do? Another key principle is that humans are not infinitely plastic. There are biological and evolutionary constraints that shape our interactions with the world. All design is, of course, inherently political, as it is about both the provision of goods and services, but also the distribution of risks, costs and benefits. Ecological design implies robust economics, an honest assessment of human capabilities, a capacity to understand the lessons of history and past civilizations, and above all offers opportunities of healing. Designers are storytellers that aim to speak to the human spirit, and this is where education must mimic, and tell better stories about the world.

In the second article, Geoff Gurr et al indicate that ecological restoration methods must also be technically achievable and socially acceptable and spread over a range of locations. Two key aspects of agricultural biodiversity are analysed: the ways in which agricultural biodiversity may be increased to favour pest management, and the existence of a hierarchy of the types of benefits of increased biodiversity. At simple levels, structures in monocultures may be changed with new management practices to benefit natural enemies. At the other extreme, annual and perennial non-crop vegetation may be introduced to affect biodiversity on the farm or even landscape scale. There may be benefits for crop yield and quality, improved sustainability of farms, and broad societal benefits such as for recreation and aesthetics. The potential for ecological restoration of farmland to improve the sustainability of agricultural production whilst conserving biodiversity in farmscapes is high but there is still much to learn, particularly for the most efficient use of agri-environmental schemes to change land use practice.

In the third article, Cornelia Butler Flora and Jan Flora, both of Iowa State University, succinctly set out how social capital can be created in post-industrial rural communities. Two processes are occurring: the inside decay, and the incursion from outside as the suburban and disconnected sprawl brings people with different worldviews and values. Those with affluent incomes can ignore investing in social capital, as they can substitute financial capital – yet this simply results in more goods and services being imported from outside and leaves communities struggling. This article indicates that social capital can be horizontal, hierarchical or non-existent – and different patterns define different outcomes for rural communities. Diverse networks that enhance lateral learning can lead to dynamic communities able to develop new and more sustainable models of agriculture.

In the mid-1990s, one of the authors of the article by Norman Uphoff et al, speaking to the 15th World Congress of Soil Science, proposed that it was time to move soil science toward a 'second paradigm' in order to meet agricultural production needs in the tropics, and indeed in the world more generally. The prevailing paradigm, he noted, focuses primarily on production goals, and little on ecological functions. The new paradigm articulated by Sanchez addressed the particular problems of farmers who are managing marginal lands under a prevailing combination of biophysical and socioeconomic constraints: aluminium toxicity, low nutrient reserves, low water-holding capacity, high phosphorus fixation, steep slopes. For such farmers, the prescriptions of the green revolution, with its reliance on external inputs, were not working. The economic costs and logistical problems involved in procuring fertilizers and agrochemicals were prohibitive, and few of these farmers had access to irrigation, so they were dependent on rainfall with its uncertainties and insufficiencies. External inputs gave little benefit unless the water requirements of the plants and the soil (i.e. the organisms living within it) were met. The emergent 'second paradigm' is described in this final chapter of the book *Biological Approaches to Sustainable Soil Systems*. Its key themes are articulated by Sanchez in this way: 'Rely more on biological processes by adapting germplasm to adverse soil conditions, enhancing soil biological activity, and optimizing nutrient cycling to minimize external inputs and maximize the efficiency of their use.'

In the final article of this volume, North Dakota farmer Fred Kirshenmann begins by setting out the challenge of farming with the wild. As he says, his relationship with the wild has been fraught with ambiguity. He grew up believing that wildernesses would only exist in enclaves apart from agriculture. Yet this dualistic approach to land use is dysfunctional for a variety of reasons. As he says, 'the environment is constantly being constructed by the organisms (including humans) who live in it'. He goes on to describe the importance of wildness in productive farming, in terms of choice of livestock breeds, habitats for pollinators and crop rotations to eliminate herbicides. In the second part of the article, Dan Imhoff sets out the case for farming with the wild, drawing on a wide range of examples across North America. Industrialized agriculture tends to farm against the wild, and is characterized by huge monoculture fields and massive contained livestock operations. The rethinking needed to farm with the wild is already now beginning to happen – the wild farm pioneers are building alliances and developing new ways to reshape farming and food systems.

Part I

Agricultural Harm to the Environment

1

A Fable for Tomorrow

Rachel Carson

There was once a town in the heart of America where all life seemed to live in harmony with its surroundings. The town lay in the midst of a checkerboard of prosperous farms, with fields of grain and hillsides of orchards where, in spring, white clouds of bloom drifted above the green fields. In autumn, oak and maple and birch set up a blaze of colour that flamed and flickered across a backdrop of pines. Then foxes barked in the hills and deer silently crossed the fields, half hidden in the mists of the autumn mornings.

Along the roads, laurel, viburnum and alder, great ferns and wildflowers delighted the traveller's eye through much of the year. Even in winter the roadsides were places of beauty, where countless birds came to feed on the berries and on the seed heads of the dried weeds rising above the snow. The countryside was, in fact, famous for the abundance and variety of its bird life, and when the flood of migrants was pouring through in spring and autumn people travelled from great distances to observe them. Others came to fish the streams, which flowed clear and cold out of the hills and contained shady pools where trout lay. So it had been from the days many years ago when the first settlers raised their houses, sank their wells and built their barns.

Then a strange blight crept over the area and everything began to change. Some evil spell had settled on the community: mysterious maladies swept the flocks of chickens; the cattle and sheep sickened and died. Everywhere was a shadow of death. The farmers spoke of much illness among their families. In the town the doctors had become more and more puzzled by new kinds of sickness appearing among their patients. There had been several sudden and unexplained deaths, not only among adults but even among children, who would be stricken suddenly while at play and die within a few hours.

There was a strange stillness. The birds, for example – where had they gone? Many people spoke of them, puzzled and disturbed. The feeding stations in the backyards were deserted. The few birds seen anywhere were moribund; they trembled violently and could not fly. It was a spring without voices. On the mornings that had once throbbed with the dawn chorus of robins, catbirds, doves, jays, wrens and scores of other bird voices there was now no sound; only silence lay over the fields and woods and marsh.

On the farms the hens brooded, but no chicks hatched. The farmers complained that they were unable to raise any pigs – the litters were small and the young survived only a few days. The apple trees were coming into bloom but no bees droned among the blossoms, so there was no pollination and there would be no fruit.

The roadsides, once so attractive, were now lined with browned and withered vegetation as though swept by fire. These, too, were silent, deserted by all living things. Even the streams were now lifeless. Anglers no longer visited them, for all the fish had died.

In the gutters under the eaves and between the shingles of the roofs, a white granular powder still showed a few patches; some weeks before it had fallen like snow upon the roofs and the lawns, the fields and streams.

No witchcraft, no enemy action had silenced the rebirth of new life in this stricken world. The people had done it themselves.

This town does not actually exist, but it might easily have a thousand counterparts in America or elsewhere in the world. I know of no community that has experienced all the misfortunes I describe. Yet every one of these disasters has actually happened somewhere, and many real communities have already suffered a substantial number of them. A grim spectre has crept upon us almost unnoticed, and this imagined tragedy may easily become a stark reality we all shall know.

What has already silenced the voices of spring in countless towns in America? This book is an attempt to explain.

The Obligation to Endure

The history of life on earth has been a history of interaction between living things and their surroundings. To a large extent, the physical form and the habits of the Earth's vegetation and its animal life have been moulded by the environment. Considering the whole span of earthly time, the opposite effect, in which life actually modifies its surroundings, has been relatively slight. Only within the moment of time represented by the present century has one species – man – acquired significant power to alter the nature of his world.

During the past quarter century this power has not only increased to one of disturbing magnitude but it has changed in character. The most alarming of all man's assaults upon the environment is the contamination of air, earth, rivers, and sea with dangerous and even lethal materials. This pollution is for the most part irrecoverable; the chain of evil it initiates not only in the world that must support life but in living tissues is for the most part irreversible. In this now universal contamination of the environment, chemicals are the sinister and little-recognized partners of radiation in changing the very nature of the world – the very nature of its life. Strontium 90, released through nuclear explosions into the air, comes to earth in rain or drifts down as fallout, lodges in soil, enters into the grass or corn or wheat grown there, and in time takes up its abode in the bones of a human being, there to remain until his death. Similarly, chemicals sprayed on croplands or forests or gardens lie long in soil, entering into living organisms, passing from one to another in a chain of poisoning and death. Or they pass mysteriously by underground streams until they emerge and, through the alchemy of air and sunlight, combine into new forms that kill vegetation, sicken cattle, and work unknown harm on those who drink from once-pure wells. As Albert Schweitzer has said, 'Man can hardly even recognize the devils of his own creation.'

It took hundreds of millions of years to produce the life that now inhabits the earth – aeons of time in which that developing and evolving and diversifying life reached a state of adjustment and balance with its surroundings. The environment, rigorously shaping and directing the life it supported, contained elements that were hostile as well as supporting. Certain rocks gave out dangerous radiation; even within the light of the sun, from which all life draws its energy, there were short-wave radiations with power to injure. Given time – time not in years but in millennia – life adjusts, and a balance has been reached. For time is the essential ingredient; but in the modern world there is no time.

The rapidity of change and the speed with which new situations are created follow the impetuous and heedless pace of man rather than the deliberate pace of nature. Radiation is no longer merely the background radiation of rocks, the bombardment of cosmic rays, the ultraviolet of the sun that have existed before there was any life on earth; radiation is now the unnatural creation of man's tampering with the atom. The chemicals to which life is asked to make its adjustment are no longer merely the calcium and silica and copper and all the rest of the minerals washed out of the rocks and carried in rivers to the sea; they are the synthetic creations of man's inventive mind, brewed in his laboratories, and having no counterparts in nature.

To adjust to these chemicals would require time on the scale that is nature's; it would require not merely the years of a man's life but the life of generations. And even this, were it by some miracle possible, would be futile, for the new chemicals come from our laboratories in an endless stream; almost five hundred annually find their way into actual use in the US alone. The figure is staggering and its implications are not easily grasped – five hundred new chemicals to which the bodies of men and animals are required somehow to adapt each year, chemicals totally outside the limits of biologic experience.

Among them are many that are used in man's war against nature. Since the mid 1940s over two hundred basic chemicals have been created for use in killing insects, weeds, rodents and other organisms described in the modern vernacular as 'pests'; and they are sold under several thousand different brand names.

These sprays, dusts and aerosols are now applied almost universally to farms, gardens, forests, and homes – non-selective chemicals that have the power to kill every insect, the 'good' and the 'bad', to still the song of birds and the leaping of fish in the streams, to coat the leaves with a deadly film, and to linger on in soil – all this though the intended target may be only a few weeds or insects. Can anyone believe it is possible to lay down such a barrage of poisons on the surface of the earth without making it unfit for all life? They should not be called 'insecticides', but 'biocides'.

The whole process of spraying seems caught up in an endless spiral. Since DDT was released for civilian use, a process of escalation has been going on in which ever more toxic materials must be found. This has happened because insects, in a triumphant vindication of Darwin's principle of the survival of the fittest, have evolved super races immune to the particular insecticide used, hence a deadlier one has always to be developed – and then a deadlier one than that. It has happened also because, for reasons to be described later, destructive insects often undergo a 'flareback', or resurgence, after spraying, in numbers greater than before. Thus the chemical war is never won, and all life is caught in its violent crossfire.

Along with the possibility of the extinction of mankind by nuclear war, the central problem of our age has therefore become the contamination of man's total environment with such substances of incredible potential for harm – substances that accumulate in the tissues of plants and animals and even penetrate the germ cells to shatter or alter the very material of heredity upon which the shape of the future depends.

Some would-be architects of our future look towards a time when it will be possible to alter the human germplasm by design. But we may easily be doing so now by inadvertence, for many chemicals, like radiation, bring about gene mutations. It is ironic to think that man might determine his own future by something so seemingly trivial as the choice of an insect spray.

All this has been risked – for what? Future historians may well be amazed by our distorted sense of proportion. How could intelligent beings seek to control a few unwanted species by a method that contaminated the entire environment and brought the threat of disease and death even to their own kind? Yet this is precisely what we have done. We have done it, moreover, for reasons that collapse the moment we examine them. We are told that the enormous and expanding use of pesticides is necessary to maintain farm production. Yet is our real problem not one of *over-production*? Our farms, despite measures to remove acreages from production and to pay farmers *not* to produce, have yielded such a staggering excess of crops that the American taxpayer in 1962 is paying out more than one billion dollars a year as the total carrying cost of the surplus-food storage programme. And the situation is not helped when one branch of the Agriculture Department tries to reduce production while another states, as it did in 1958,

> It is believed generally that reduction of crop acreages under provisions of the Soil Bank will stimulate interest in use of chemicals to obtain maximum production on the land retained in crops.

All this is not to say there is no insect problem and no need of control. I am saying, rather, that control must be geared to realities, not to mythical situations, and that the methods employed must be such that they do not destroy us along with the insects.

The problem whose attempted solution has brought such a train of disaster in its wake is an accompaniment of our modern way of life. Long before the age of man, insects inhabited the earth – a group of extraordinarily varied and adaptable beings. Over the course of time since man's advent, a small percentage of the more than half a million species of insects have come into conflict with human welfare in two principal ways: as competitors for the food supply and as carriers of human disease.

Disease-carrying insects become important where human beings are crowded together, especially under conditions where sanitation is poor, as in time of natural disaster or war or in situations of extreme poverty and deprivation. Then control of some sort becomes necessary. It is a sobering fact, however, as we shall presently see, that the method of massive chemical control has had only limited success, and also threatens to worsen the very conditions it is intended to curb.

Under primitive agricultural conditions the farmer had few insect problems. These arose with the intensification of agriculture – the devotion of immense acreages to a single crop. Such a system set the stage for explosive increases in specific insect populations. Single-crop farming does not take advantage of the principles by which nature works; it is agriculture as an engineer might conceive it to be. Nature has introduced great variety into the landscape, but man has displayed a passion for simplifying it. Thus he undoes the built-in checks and balances by which nature holds the species within bounds. One important natural check is a limit on the amount of suitable habitat for each species. Obviously then, an insect that lives on wheat can build up its population to much higher levels on a farm devoted to wheat than on one in which wheat is intermingled with other crops to which the insect is not adapted.

The same thing happens in other situations. A generation or more ago, the towns of large areas of the US lined their streets with the noble elm tree. Now the beauty they hopefully created is threatened with complete destruction as disease sweeps through the elms, carried by a beetle that would have only a limited chance to build up large populations and to spread from tree to tree if the elms were only occasional trees in a richly diversified planting.

Another factor in the modern insect problem is one that must be viewed against a background of geologic and human history: the spreading of thousands of different kinds of organisms from their native homes to invade new territories. This worldwide migration has been studied and graphically described by the British ecologist Charles Elton in his recent book *The Ecology of Invasions by Animals and Plants* (1958). During the Cretaceous Period, some 100 million years ago, flooding seas cut many land bridges between continents and living things found themselves confined in what Elton calls 'colossal separate nature reserves'. There, isolated from others of their kind, they developed many new species. When some of the land masses were joined again, about 15 million years ago, these species began to move out into new territories – a movement that is not only still in progress but is now receiving considerable assistance from man.

The importation of plants is the primary agent in the modern spread of species, for animals have almost invariably gone along with the plants, quarantine being a comparatively recent and not completely effective innovation. The United States Office of Plant Introduction alone has introduced almost 200,000 species and varieties of plants from all over the world. Nearly half of the 180 or so major insect enemies of plants in the US are accidental imports from abroad, and most of them have come as hitch-hikers on plants.

In new territory, out of reach of the restraining hand of the natural enemies that kept down its numbers in its native land, an invading plant or animal is able to become enormously abundant. Thus it is no accident that our most troublesome insects are introduced species.

These invasions, both the naturally occurring and those dependent on human assistance, are likely to continue indefinitely. Quarantine and massive chemical campaigns are only extremely expensive ways of buying time. We are faced, according to Dr Elton, 'with a life-and-death need not just to find new technological means of suppressing this plant or that animal'; instead we need the basic knowledge of animal populations and their relations to their surroundings that will 'promote an even balance and damp down the explosive power of outbreaks and new invasions'.

Much of the necessary knowledge is now available but we do not use it. We train ecologists in our universities and even employ them in our governmental agencies but we seldom take their advice. We allow the chemical death rain to fall as though there were no alternatives whereas in fact there are many, and our ingenuity could soon discover many more if given opportunity. Have we fallen into a mesmerized state that makes us accept as inevitable that which is inferior or detrimental, as though having lost the will or the vision to demand that which is good? Such thinking, in the words of the ecologist Paul Shepard,

> idealizes life with only its head out of water, inches above the limits of toleration of the corruption of its own environment... Why should we tolerate a diet of weak poisons, a home in insipid surroundings, a circle of acquaintances who are not quite our enemies, the noise of motors with just enough relief to prevent insanity? Who would want to live in a world which is just not quite fatal?

Yet such a world is pressed upon us. The crusade to create a chemically sterile, insect-free world seems to have engendered a fanatic zeal on the part of many specialists and most of the so-called control agencies. On every hand there is evidence that those engaged in spraying operations exercise a ruthless power. 'The regulatory entomologists … function as prosecutor, judge and jury, tax assessor and collector and sheriff to enforce their own orders', said Connecticut entomologist Neely Turner. The most flagrant abuses go unchecked in both state and federal agencies.

It is not my contention that chemical insecticides must never be used. I do contend that we have put poisonous and biologically potent chemicals indiscriminately into the hands of persons largely or wholly ignorant of their potentials for harm. We have subjected enormous numbers of people to contact with these poisons, without their consent and often without their knowledge. If the Bill of Rights contains no guarantee that a citizen shall be secure against lethal poisons distributed either by private individuals or by public officials, it is surely only because our forefathers, despite their considerable wisdom and foresight, could conceive of no such problem.

I contend, furthermore, that we have allowed these chemicals to be used with little or no advance investigation of their effect on soil, water, wildlife and man himself. Future generations are unlikely to condone our lack of prudent concern for the integrity of the natural world that supports all life.

There is still very limited awareness of the nature of the threat. This is an era of specialists, each of whom sees his own problem and is unaware of or intolerant of the larger frame into which it fits. It is also an era dominated by industry, in which the right to make a dollar at whatever cost is seldom challenged. When the public protests, confronted with some obvious evidence of damaging results of pesticide applications, it is fed little tranquillizing pills of half truth. We urgently need an end to these false assurances, to the sugar coating of unpalatable facts. It is the public that is being asked to assume the risks that the insect controllers calculate. The public must decide whether it wishes to continue on the present road, and it can do so only when in full possession of the facts. In the words of Jean Rostand, 'The obligation to endure gives us the right to know.'

The Real Costs of Food

When we buy or bake our daily bread, do we ever wonder about how much it really costs? We like it when our food is cheap, and complain when prices rise. Indeed, riots over food prices date back at least to Roman times. Governments have long since intervened to keep food cheap in the shops, and tell us that policies designed to do exactly this are succeeding. In most industrialized countries, the proportion of the average household budget spent on food has been declining in recent decades. Food is getting cheaper relative to other goods, and many believe that this must benefit everyone as we all need to eat food. But we have come to believe a damaging myth. Food is not cheap. It only appears cheap in the shop because we are not encouraged to think of the hidden costs of damage caused to the environment and human health by certain systems of agricultural production. Thus we actually pay three times for our food. Once at the till in the shop, a second time through taxes that are used to subsidize farmers or support agricultural development, and a third time to clean up the environmental and health side effects. Food looks cheap because we count these costs elsewhere in society. As economists put it, the real costs are not internalized in prices.[1]

This is not to say that prices in the shop should rise, as this would penalize the poor over the wealthy. Using taxes to raise money to support agricultural development is also potentially progressive, as the rich pay proportionally more in taxes, and the poor, who spend proportionally more of their budget on food, benefit if prices stay low. But this idea of fairness falters when set against the massive distortions brought about by modern agricultural systems that additionally impose large environmental and health costs throughout economies. Other people and institutions pay these costs, and this is both unfair and inefficient. If we were able to add up the real costs of producing food, we would find that modern industrialized systems of production perform poorly in comparison with sustainable systems. This is because we permit cost-shifting – the costs of ill health, lost biodiversity

Reprinted from Pretty J. 2002. Reality Cheques, in Pretty J. *Agri-culture*. Earthscan, London.

and water pollution are transferred away from farmers, and so not paid by those producing the food nor included in the price of the products sold. Until recently, though, we have lacked the methods to put a price on these side effects.

When we conceive of agriculture as more than simply a food factory, indeed as a multifunctional activity with many side effects, then this idea that farmers do only one thing must change. Of course, it was not always like this. It is modern agriculture that has brought a narrow view of farming, and it has led us to crisis. The rural environment in industrialized countries suffers, the food we eat is as likely to do as much harm as good, and we still think food is cheap. The following words were written more than 50 years ago, just before the advent of modern industrialized farming.

> Why is there so much controversy about Britain's agricultural policy, and why are farmers so disturbed about the future?... After the last war, the people of these islands were anxious to establish food production on a secure basis, yet, in spite of public good will, the farming industry has been through a period of insecurity and chaotic conditions.

These are the opening words to a national enquiry that could have been written about a contemporary crisis. Yet they are by Lord Astor, written in 1945 to introduce the Astor and Rowntree review of agriculture. This enquiry was critical of the replacement of mixed methods with standardized farming. They said, 'to farm properly you have got to maintain soil fertility; to maintain soil fertility you need a mixed farming system'. They believed that farming would only succeed if it maintained the health of the whole system, beginning in particular with the maintenance of soil fertility: 'obviously it is not only sound business practice but plain common sense to take steps to maintain the health and fertility of soil'.[2]

But in the enquiry, some witnesses disagreed, and called for a 'specialised and mechanised farming', though interestingly, the farming establishment at the time largely supported the idea of mixed farming. But in the end, the desire for public subsidies to encourage increases in food production took precedence, and these were more easily applied to simplified systems than mixed ones. The 1947 Agriculture Act was the outcome, a giant leap forward for modern, simplified agriculture, and a large step away from farming that valued nature's assets for farming. Sir George Stapledon, a British scientist knighted for his research on grasslands, was another perceptive scientist well ahead of his time. He too was against monocultures and in favour of diversity, arguing in 1941 that 'senseless systems of monoculture designed to produce food and other crops at the cheapest possible cost have rendered waste literally millions of acres of once fertile or potentially fertile country'.[3] In his final years, just a decade after the 1947 Act, he said:

> today technology has begun to run riot and amazingly enough perhaps nowhere more so than on the most productive farms... Man is putting all his money on narrow specialisation and on the newly dawned age of technology has backed a wild horse which given its head is bound to get out of control.

Wise words from eminent politicians and scientists. But lost on the altar of progress. Until now, perhaps, as new ideas on agriculture have begun to emerge and gather credence.

Agriculture's Unique Multifunctionality

We should all now be asking: what is farming for? Clearly, in the first instance, to produce food, and we have become very good at it. A great success, but only if our measures of efficiency are narrow. Agriculture is unique as an economic sector. It does more than just produce food, fibre, oil and timber. It has a profound impact on many aspects of local, national and global economies and ecosystems. These impacts can be either positive or negative. The negative ones are worrying. Pesticides and nutrients leaching from farms have to be removed from drinking water, and these costs are paid by water consumers, not by the polluters. The polluters, therefore, benefit by not paying to clean up the mess they have created, and have no incentive to change behaviour. What also makes agriculture unique is that it affects the very assets on which it relies for success. Agricultural systems at all levels rely for their success on the value of services flowing from the total stock of assets that they control, and five types of asset, natural, social, human, physical and financial capital, are now recognized as being important.[4]

Natural capital produces nature's goods and services, and comprises food, both farmed and harvested or caught from the wild, wood and fibre; water supply and regulation; treatment, assimilation and decomposition of wastes; nutrient cycling and fixation; soil formation; biological control of pests; climate regulation; wildlife habitats; storm protection and flood control; carbon sequestration; pollination; and recreation and leisure. *Social capital* yields a flow of mutually beneficial collective action, contributing to the cohesiveness of people in their societies. The social assets comprising social capital include norms, values and attitudes that predispose people to cooperate; relations of trust, reciprocity and obligations; and common rules and sanctions mutually agreed or handed-down. These are connected and structured in networks and groups.

Human capital is the total capability residing in individuals, based on their stock of knowledge skills, health and nutrition. It is enhanced by access to services that provide these, such as schools, medical services and adult training. People's productivity is increased by their capacity to interact with productive technologies and with other people. Leadership and organizational skills are particularly important in making other resources more valuable. *Physical capital* is the store of human-made material resources, and comprises buildings, such as housing and factories, market infrastructure, irrigation works, roads and bridges, tools and tractors, communications, and energy and transportation systems, that make labour more productive. *Financial capital* is more of an accounting concept, as it serves as a facilitating role rather than as a source of productivity in and of itself. It represents accumulated claims on goods and services, built up through financial systems that gather savings and issue credit, such as pensions, remittances, welfare payments, grants and subsidies.

As agricultural systems shape the very assets on which they rely for inputs, a vital feedback loop occurs from outcomes to inputs. Donald Worster's three principles for good farming capture this idea. It is farming that makes people healthier, farming that promotes a more just society, and farming that preserves the earth and its networks of life. He says 'the need for a new agriculture does not absolve us from the moral duty and common-sense advice to farm in an ecologically rational way. Good farming protects the land, even when it uses it.'[5] Thus sustainable agricultural systems tend to have a positive effect on natural, social and human capital, whilst unsustainable ones feed back to deplete these assets, leaving less for future generations. For example, an agricultural system that erodes soil whilst producing food externalizes costs that others must bear. But one that sequesters carbon in soils through organic matter accumulation helps to mediate climate change. Similarly, a diverse agricultural system that enhances on-farm wildlife for pest control contributes to wider stocks of biodiversity, whilst simplified modernized systems that eliminate wildlife do not. Agricultural systems that offer labour-absorption opportunities, through resource improvements or value-added activities, can boost economies and help to reverse rural-to-urban migration patterns.

Agriculture is, therefore, fundamentally multifunctional. It jointly produces many unique non-food functions that cannot be produced by other economic sectors so efficiently. Clearly, a key policy challenge, for both industrialized and developing countries, is to find ways to maintain and enhance food production. But the key question is: can this be done whilst seeking both to improve the positive side effects and to eliminate the negative ones? It will not be easy, as past agricultural development has tended to ignore both the multifunctionality of agriculture and the pervasive external costs.[6]

This leads us to a simple and clear definition for sustainable agriculture. It is farming that makes the best use of nature's goods and services whilst not damaging the environment.[7] It does this by integrating natural processes such as nutrient cycling, nitrogen fixation, soil regeneration and natural enemies of pests into food production processes. It also minimizes the use of non-renewable inputs that damage the environment or harm the health of farmers and consumers. It makes better use of the knowledge and skills of farmers, so improving their self-reliance, and it makes productive use of people's capacities to work together to solve common management problems. Through this, sustainable agriculture also contributes to a range of public goods, such as clean water, wildlife, carbon sequestration in soils, flood protection and landscape quality.

Putting Monetary Values on Externalities

Most economic activities affect the environment, either through the use of natural resources as an input or by using the 'clean' environment as a sink for pollution. The costs of using the environment in this way are called externalities. As they are side effects of the economic activity, they are external to markets, and so their costs are not part of the prices paid by producers or consumers. When such externalities are not included in prices, they distort the market by encouraging activities that are costly to society even if the private benefits are substantial. The types of externalities encountered in the agricultural sector have several features. Their costs are often neglected, and frequently occur with a time lag. They often damage groups whose interests are not represented, and the identity of the producer of the externality is not always known.[8]

In practice, there is little agreed data on the economic cost of agricultural externalities. This is partly because the costs are highly dispersed and affect many sectors of economies. It is also necessary to know about the value of nature's goods and services, and what happens when these largely unmarketed goods are lost. As the current system of economic accounting grossly underestimates the current and future value of natural capital, this makes the task even more difficult.[9] It is relatively easy, for example, to count the treatment costs following pollution, but much more difficult to value, for example, skylarks singing on a summer's day, and the costs incurred when they are lost.

Several studies have recently put a cost on the negative externalities of agriculture in China, Germany, The Netherlands, the Philippines, the UK and the US.[10] When it is possible to make the calculations, our understanding of what is the best or most efficient form of agriculture can change rapidly. In the Philippines, researchers from the International Rice Research Institute (IRRI) found that modern rice cultivation was costly to human health. They investigated the health status of rice farmers exposed to pesticides, and estimated the monetary costs of significantly increased incidence of eye, skin, lung and neurological disorders. By incorporating these into the economics of pest control, they found that modern, high-pesticide systems suffer twice, as with nine pesticide sprays per season they returned less per hectare than the integrated pest management strategies, and cost the most in terms of ill health. Any expected positive production benefits of applying pesticides were overwhelmed by the health costs. Rice production using natural control methods has multifunctionality in contributing positively both to human health as well as sustaining food production.[11]

At the University of Essex, we recently developed a new framework to study the negative externalities of UK agriculture. This uses seven cost categories to assess negative environmental and health costs – damage to water, air, soil and biodiversity, and damage to human health by pesticides, microorganisms and disease agents. The analysis of damage and monitoring costs counted only external costs, as private costs borne by farmers themselves, such as from increased pest or weed resistance from pesticide overuse, are not included. We conservatively estimated that the external costs of UK agriculture, almost all of which is modernized and industrialized, to be at least £1½–2 billion each year. Another study by Olivia Hartridge and David Pearce has also put the annual costs of modern agriculture in excess of £1 billion.[12] These are costs imposed on the rest of society, and effectively a hidden subsidy to the polluters.[13] The annual costs arise from damage to the atmosphere (£316 million), to water (£231 million), to biodiversity and landscapes (£126 million), to soils (£96 million) and to human health (£777 million).

Using a similar framework of analysis, the external costs in the US amount to nearly £13 billion per year.[14]

How do all these costs arise? Pesticides, nitrogen and phosphorus nutrients, soil, farm wastes and microorganisms escape from farms to pollute ground and surface water. Costs are incurred by water delivery companies, and then passed onto their customers, to remove these contaminants, to pay for restoring watercourses following pollution incidents and eutrophication, and to remove soil from water. Using UK water companies' returns for both capital and operating expenditure, we estimated annual external costs to be £125 million for the removal of pesticides below legal standards, £16 million for nitrate, £69 million for soil, and £23 million for *Cryptosporidium*.[15] These costs would be much greater if the policy goal were complete removal of all contamination.

Agriculture also contributes to atmospheric pollution through the emissions of four gases: methane from livestock, nitrous oxide from fertilizers, ammonia from livestock wastes and some fertilizers, and carbon dioxide from energy and fossil fuel consumption and loss of soil carbon. These in turn contribute to atmospheric warming (methane, nitrous oxide and carbon dioxide), ozone loss in the stratosphere (nitrous oxide), acidification of soils and water (ammonia) and eutrophication (ammonia). The annual cost for these gases is some £310 million.[16] A healthy soil is vital for agriculture, but modern farming has accelerated erosion, primarily through the cultivation of winter cereals, the conversion of pasture to arable, the removal of field boundaries and hedgerows, and overstocking of livestock on grasslands. Off-site costs arise when soil carried off farms by water or wind blocks ditches and roads, damages property, induces traffic accidents, increases the risk of floods, and pollutes water through sediments and associated nitrate, phosphate and pesticides. These amount to £14 million per year. Carbon in organic matter in soils is also rapidly lost when pastures are ploughed or when agricultural land is intensively cultivated, and adds another £82 million to the annual external costs.

Modern farming has had a severe impact on wildlife in the UK. More than nine-tenths of wildflower-rich meadows have been lost since the 1940s, together with a half of heathland, lowland fens, and valley and basin mires, and a third to a half of ancient lowland woods and hedgerows. Species diversity is also declining in the farmed habitat itself. Increase use of drainage and fertilizers has led to grass monocultures replacing flower-rich meadows, overgrazing of uplands has reduced species diversity, and herbicides have cut diversity in arable fields. Hedgerows were removed at a rate of 18,000 kilometres a year between the mid-1980s and 1990s. Farmland birds have particularly suffered, with the populations of nine species falling by more than a half in the 25 years to 1995.[17] The costs of restoring species and habitats under Biodiversity Action Plans were used as a proxy for the costs of wildlife and habitat losses, and together with the costs of replacing hedgerows, stonewalls and bee colonies, bring the annual costs to £126 million.

Pesticides can affect workers engaged in their manufacture, transport and disposal, operators who apply them in the field, and the general public. But there is still great uncertainty because of differing risks per product, poor understanding of chronic effects, such as in cancer causation, weak monitoring systems, and misdiagnoses by doctors.[18] For these reasons, it is very difficult to say exactly how many people are affected by pesticides each year. According to voluntary reporting to government, one to two hundred incidents occur each year in the UK.[19] However, a recent government survey of 2000 pesticide users found that 5 per cent reported at least one symptom in the past year and about which they had consulted a doctor, and a further 10 per cent had been affected, mostly by headaches, but had not consulted a doctor, incurring annual costs of about £1 million. Chronic health hazards associated with pesticides are even more difficult to assess. Pesticides are ingested via food and water, and these represent some risk to the public. With current scientific knowledge, it is impossible to state categorically whether or not certain pesticides play a role in cancer causation. Other serious health problems arising from agriculture are foodborne illnesses, antibiotic resistance and BSE-CJD.[20]

These external costs of UK agriculture are alarming. They should call into question what we mean by efficiency. Farming receives £3 billion of public subsidies each year, yet causes another £1½ billion of costs elsewhere in the economy. If we had no alternatives, then we would have to accept these costs. But, in every case, there are choices. Pesticides do not have to get into water. Indeed, they do not need to be used at all in many farm systems. The pesticide market in the UK is £500 million pounds, yet we pay £120million just to clean them out of drinking water. We do not need farming that damages biodiversity and landscapes; we do not need intensive livestock production that encourages infections and overuse of antibiotics. Not all costs, though, are subject to immediate elimination with sustainable methods of production. Cows will still belch methane, until animal feed scientists find a way of amending ruminant biochemistry to prevent its emission. But it is clear that many of these massive distortions could be removed with some clear thinking, firm policy action and brave action by farmers.[21]

The Side Effects of Intensive Food Production on Water and Wetlands

One problem with the redesign of landscape for modern agriculture is that important natural features and functions are lost. Watercourses and bodies are one of the most tamed and abused features. Wetlands have been drained, rivers straightened or hidden behind levees, aquifers mined, and rivers, lakes and seas polluted, mostly to ensure that productive farmland is protected from harm or excessive costs. Once again, though, the narrow view of the value of farmland for food production above all other uses has caused secondary problems. According to the National Research Council, 47 million hectares of wetlands in the US were drained in the past two centuries, and 85 per cent of inland waters are now artificially controlled. This created new farmland, to the benefit of farmers. But remove the wetlands, and the many valued services they provide are also lost. They are habitats for biodiversity, capture nutrients that run off fields, provide flood protection and are important cultural features of the landscape.

Donald Worster describes growing up within 30 metres of the already tamed Cow Creek in Kansas: 'we could not see it from our windows; we could only see the levee'. In the 19th century, as the town had expanded by the river, and the early settlers converted land to wheat cultivation, so the normal and regular flooding of the river started to cause considerable economic damage. Episodes of flooding and continued expenditure on flood protection continued for decades, until a major flood in 1941 finally led the Army Corps of Engineers to construct a series of 4-metre-high levees: 'now at long last the good Kansas folk, having vanquished the Indians and the bison and the sandhill cranes and the antelope, had managed to vanquish Cow Creek. Abruptly, it disappeared from their lives.' This is the alarming part. When valued landscape features have gone, or have been replaced, the everyday experiences of local people will steadily erode old memories. The young will not know, while the old will be troubled, until they pass on too.[22] Meanwhile, we all lose.

In Europe, river valleys used to contain many water meadows, fields likely to be flooded by overflowing rivers, and so used productively to produce a late winter or early spring crop of grass. More importantly, when the river did flood, water was stored on the meadows, and did not harm housing or other vulnerable areas. But in the drive towards intensification of food production, most of these meadows have been converted to arable fields. At the same time, rivers have been tamed through channelling, field sizes increased, hedgerows removed, and houses built on vulnerable land. Now, when it rains, the consequence is increased flooding to vulnerable areas. It looks as though there has been 'too much' rain, but in truth it is largely due to changes in the landscape.

In Germany, Rienk van der Ploeg and colleagues have correlated loss of meadows with an increased incidence of inland floods, with 6 of the 12 most extreme events over a century having occurred since 1983. They show that changes in the diversity of use of agricultural land are the main cause. In particular, permanent meadows have been converted to arable fields, some 1½ million hectares since the mid-1960s, which because of surface sealing and compaction are less likely to hold water during winter. Another 4½ million hectares of wetland soils have been drained since the 1940s. Thus when it rains, water contributes more rapidly to river water discharge, so increasing the likelihood of flooding. The cost of two floods in 1993 and 1995 were nearly DM2 billion, and van der Ploeg concludes that the conversion of arable back to permanent meadows would be economically and environmentally beneficial: 'it must be acknowledged that any further increase in agricultural productivity is likely to cause additional adverse environmental effects. Future farm policy must pay more attention to the environment'.[23]

Japan provides another example of the wider value of agricultural wetlands, in this case irrigated paddy rice fields. Japan's very high rainfall is concentrated into a few months on a landscape characterized by a high mountain chain. With a very short flow time to the sea, this means that much of the country is subject to severe flood risk. Paddy rice farming, though, provides an important sink for this water.

There are more than 2 million hectares of paddy rice in Japan, and each of these hectares holds about 1000 tonnes of water each year. In the Koshigaya City basin, 25 kilometres north of Tokyo, paddy fields close to the city have been steadily converted to residential uses over the past quarter century. But as the area of paddy has declined by about 1000 hectares since the mid-1970s, so the incidence of flooding has increased. Each year, 1000–3000 houses are flooded. In whole watersheds, woods and farms on steep slopes have been identified as having the greatest value in buffering and slowing water flow, and minimizing landslides. Diversity, though, is critical. As Yoshitake Kato and colleagues have put it:

> traditional villages in rural areas include settlements, paddy fields, crop fields and forested hills or mountains, all as linked landscape. The systems were dependent on all their parts. The decline of farming in the uplands, together with loss of forests, threatens the stability of whole watersheds.[24]

In China, the 500,000 hectares of wetlands that have been reclaimed for crop production in the past 50 years have meant the loss of flood-water storage capacity of some 50 billion cubic metres, a major reason for the $20 billion flood damage caused in 1998.[25] In many agricultural systems, over-intensive use of the land has resulted in sharp declines in soil organic matter and/or increases in soil erosion, some of which in turn threatens the viability of agriculture itself. In South Asia, for example, a quarter of farmland is affected by water erosion, a fifth by wind erosion, and a sixth by salinization and waterlogging.[26]

Putting a value on wetlands and watercourses, so that we can calculate how much is lost when they are damaged or destroyed, is not a trivial task. Economists have no agreed value for wetlands, though various studies indicate that individual bodies can provide several million dollars of free services to nearby communities for waste assimilation and treatment. A recent US Department of Agriculture study put wetland monetary value at $300,000 per hectare per year. Another way to assess value is to investigate how much people pay to visit wetlands, whether to watch or photograph biodiversity, or indeed to shoot it. In the US, it is estimated that 50 million people each year spend $10 billion observing and photographing wetland flora and fauna, 31 million anglers spend $16 billion on fishing, and 3 million waterfowl hunters spend nearly $700 million annually on shooting it. A recent meta-analysis of economic studies of people's willingness-to-pay for recreational services of wetlands and watercourses puts the average value in Europe to be £20–25 per person per hectare per year.[27] Thus each hectare of wetland converted to another purpose means the loss of at least £20 of value to the public. There are, of course, limitations in these exercises, as monetary values cannot be allocated to all uses.

One of the most serious side effects of agriculture is the leaching and run-off of nutrients, and their disruption of water ecosystems. Eutrophication is the term used to describe nutrient enrichment of water that leads to excessive algal growth, disruption of whole food webs, and in the worst cases complete eradication of all life through deoxygenation. The most notorious example is the Gulf of Mexico dead-zone, an area of 5000–18,000km^2 of sea that has received so much nutrient input that all aquatic life has been killed. The cost of farm overuse of nutrients in the Mississippi basin is thus borne by the fishing families of Louisiana. No one has yet put a cost on these losses, yet if they were internalized in the prices of fertilizers, or the activities of intensive livestock units, we would expect to see much greater care shown about such polluting activities.[28]

At the University of Essex, we recently conducted a study of the costs of nutrient enrichment of water in the UK.[29] Eutrophication affects the value of waterside properties, and reduces the recreational and amenity value of water bodies for water sports, angling and general amenity, for industrial uses, for the tourist industry and for commercial aquaculture, fisheries and shell-fisheries. Additional costs are incurred through a variety of social responses by both statutory and non-statutory agencies. In total, we estimate nutrient enrichment to cost some £150 million per year in the UK.[30]

Industrialized Agriculture and Foodborne Illnesses

Having mostly conquered hunger in industrialized countries, it is a sad irony that food is now a major source of ill health. We eat too much, we eat the wrong mix of foods, and we get ill from foodborne illnesses. In Europe, 10–20 per cent of all people are defined as obese, with a body mass index greater than 30kg per square metre. The World Health Organization estimates that 2–7 per cent of health care costs in Europe arise from obesity, and one American study suggests that a 10 per cent weight loss amongst obese people would increase life expectancy by 2–7 months, and produce lifetime benefits of US$2000–6000 per person.[31] Several diseases are strongly linked to unbalanced food consumption, including non-insulin dependent diabetes, the incidence of which is growing rapidly, together with strokes, coronary heart disease and some cancers.

Many of these health problems, though, are attributable to the choices consumers make. We could eat five portions of fruit and vegetable per day, thus protecting against many of these problems, but for a variety of reasons we do not. But we cannot choose when it comes to foodborne diseases. The WHO estimates that 130 million people in Europe are affected by foodborne diseases each year, mainly from biological sources, particularly strains of *Salmonella*, *Campylobacter*, *Listeria* and *E. coli*. *Salmonella* is the most common pathogen, accounting for up to 90 per cent of cases in some countries. Throughout the world, diarrhoea is the most common symptom of foodborne illness, and is a major cause of death and retardation of growth in infants. There is evidence that cases of *Campylobacter* and *Salmonella* poisoning are increasing in Europe, though some of the increases can be explained by better monitoring systems.[32] In the US, the incidence of foodborne illness is greater, perhaps because of the greater industrialization of agriculture and, in particular, of livestock raising. According to the government's Centers for Disease

Control, 76 million people in the US fall ill each year from foodborne illness, of whom more than 300,000 are hospitalized and 5000 die.[33]

The costs of foodborne illnesses are massive. For the US, the Institute for Medicine at the National Academy of Sciences, the US Department of Agriculture (USDA) and the World Health Organization estimates them to be between $34 and $110 billion dollars per year. In the UK, the government's Food Standards Agency estimates that each of the annual 5 million cases of food poisoning costs on average £85 for costs to health services and losses to businesses, putting the annual cost at more than £400 million. These data suggest that one in four Americans and one on ten Britons suffer from food poisoning each year.[34]

Some of these foodborne illnesses arise from shellfish, others are associated with mass catering or occur in the food processing chain. But it is the initial sources of infection on the farm, combined with the overuse of antibiotics for growth promotion, that is an increasing source of disquiet. The concentration of livestock into factory feedlots, broiler sheds and colossal pig units promotes infection and spread. As the WHO puts it 'the greatest risk appears to be the production of animal foods. It is from this source that the most serious health threats originate, for instance, Salmonella, Campylobacter, E.coli and Yersinia.' The pool of infection at the start of the food chain is now very serious. The USDA has found very high levels of microbial infections in US farm animals, particularly in broiler chickens and turkeys. *Clostridium* has been found in 30–40 per cent of flocks, *Campylobacter* in nearly 90 per cent, *Salmonella* in 20–30 per cent, and *Staphylococcus* in 65 per cent. These levels of infection are matched in some European countries, with more than 90 per cent of pig herds and nearly 50 per cent of cattle in The Netherlands and Denmark contaminated with *Campylobacter*. At these levels of incidence in animals, it is hardly surprising that illness incidence from meat consumption is so high. Incidence in pigs and cattle is much lower, but still a worrying 3–30 per cent of herds for these four pathogens (Table 2.1).

This extraordinary problem, slipping quietly behind a desire for ever-cheaper foods, is worsened by antibiotic resistance brought on by overuse of antibiotics for livestock growth promotion and over-prescription in medicine. Twenty-three thousand tonnes of antibiotics are used in the US each year, of which 11 thousand are given to animals, four-fifths of which is just for growth promotion. In the UK, 1200 tonnes of antibiotics are used each year, 40 per cent of which is for humans,

Table 2.1 *Incidence of microbial infection in farm animals, US*

	Proportion of individuals with infectious bacteria (%)			
	Broiler chickens	*Turkeys*	*Pigs*	*Cattle*
Clostridium	43	29	10	8
Campylobacter	88	90	32	1
Salmonella	29	19	8	3
Staphylococcus	65	65	16	8

30 per cent for farm animals, and 30 per cent for domestic pets and horses. Only one-fifth of the antibiotics and other antimicrobials used in modern agriculture are for therapeutic treatment of clinical diseases, with four-fifths for prophylactic use and growth promotion. The Centers for Disease Control say, 'antimicrobial resistance is a serious clinical and public health problem in the US', and one estimate from the Institute of Medicine suggests that such resistance costs $30 million per year. A UK House of Lords select committee enquiry was even more alarmed, recently stating, 'there is a continuing threat to human health from the imprudent use of antibiotics in animals … we may face the dire prospect of revisiting the pre-antibiotic era'.[35]

In both Europe and North America, the most common forms of antimicrobial resistance are to strains of antibiotics used in treating animals, and these are transferred to human patients. Some antibiotics, such as fluoroquinones and avoparcin, used to treat infections in poultry and as growth promoters, are now associated with dramatic increases in resistant diseases in humans. Fluoroquinone resistance is thought to be the main factor why *Campylobacter* infections have become so common in The Netherlands. As the WHO puts it, '*Campylobacter* species are now the commonest cause of bacterial gasteroenteritis is developed countries, and cases are predominantly associated with consumption of poultry'.[36] There is no such thing as a cheap chicken.

Putting a Monetary Value on Agricultural Landscapes

Landscapes are culturally valuable, and the aesthetic value we gain from them owes much to their emergence from agricultural practices. They are, of course, almost impossible to value in monetary terms. However, many proxies can be used, including how much governments are willing to pay farmers to produce certain habitats or landscapes, how often the public visits the countryside, and how much they spend when they get there. In the UK, several studies of agri-environmental policies have sought to put a value on positive environmental and landscape outcomes.[37] These schemes have attempted to restore some of the habitat and other positive countryside attributes that were lost during intensification as well as protect those attributes not yet lost.

UK agri-environmental schemes have been designed to deliver benefits in several forms, including biodiversity, landscape patterns, water quality, archaeological sites and enhanced access. Benefits may accrue to those in the immediate area of a scheme, to visitors from outside the area and to the public at large. The annual per-household benefits, using a variety of valuation methods such as contingent valuation, choice experiments and contingent ranking, vary from £2 to £30 pounds for most Environmentally Sensitive Areas, rising to £140 for the Norfolk Broads and £380 for Scottish machair grasslands. If we take the range of annual benefits per household to be £10–30, and assume that this is representative of the average households' preferences for all landscapes produced by agriculture, then this suggests national benefits of the order of £200–600 million. Expressed on a per hectare basis, this suggests annual benefits of £20–60 per hectare of arable and pasture land in the UK.

On the one hand, these are likely to be overestimates, assuming agri-environment schemes have already targeted certain landscapes because of their higher value. On the other hand, they could be substantial underestimates, as they omit to value such benefits as pathogen-free foods, uneroded soils, emission-free agriculture and biodiversity-producing systems, as well as focusing on the outcomes of a scheme rather than the whole landscape. There are too few studies yet to corroborate these data. One study in the UK compared paired organic and non-organic farms, and concluded that organic agriculture produces £75–125 per hectare of positive externalities each year, with particular benefits for soil health and wildlife.[38] As there are 3 million hectares of organic farming in Europe, the annual positive externalities could be £300 million, assuming benefits hold for the many organic farming systems across Europe.

Actual visits made to the countryside are another proxy measure of how much we value landscapes. Each year in the UK, day and overnight visitors make some 433 million visit-days to the countryside and another 118 million to the seaside.[39] The average spend per day or night varies from nearly £17 for UK day visitors, to £33 for UK overnight visitors, and just over £58 for overseas overnight visitors. This indicates that the 551 million visit-days to the countryside and seaside result in spending of £14 billion per year. This is three and a half times greater than the annual public subsidy of farming, and indicates just how much we value the landscape.

If it is clean water that is required, the value of an agricultural landscape can be substantial, as New York State has found out with its support for sustainable agriculture in the 500,000 hectare Catskill-Delaware watershed complex.[40] New York City gets 90 per cent of its drinking water from these watersheds, some 6 billion litres a day. In the late 1980s, though, the city was faced with having to construct a filtration facility to meet new drinking water standards, the cost of which would be $5–8 billion, plus another $200–500 million in annual operating costs. A third of the cropland in the watershed would have to be taken out of farming so as to reduce run-off of eroded soil, pesticides, nutrients and bacterial and protozoan pathogens.

Instead, the city opted for a collaborative approach with farmers. It supported the establishment of a Watershed Agricultural Council in the early 1990s, a partnership of farmers, government and private organizations with the dual aim of protecting the city's drinking water supply and sustaining the rural economy. It works on whole farm planning with each farm, tailoring solutions to local conditions to maximize reductions in off-site costs. The first two phases of the programme leading to the 85 per cent target in pollution reduction cost some $100 million, a small proportion of the cost of the filtration plant and its annual costs. Not only do taxpayers benefit from this approach to joint agri-environmental management, but so do farmers, the environment and rural economies.[41] The only surprising thing is that these initiatives are still rare.

Agriculture's Carbon Dividend

The greatest environmental problem we face anywhere in the world is now climate change, provoked by rising levels of anthropogenic greenhouse gases. It threatens to disrupt economies and ecosystems, challenge existing land uses, substantially raise sea levels, and drown coastal lands and even some whole countries. To slow down and eventually to reverse these changes, we need to reduce human-induced emissions of these gases, as well as find ways to capture or lock up carbon from the atmosphere. Sustainable agriculture can make an important contribution to climate change mitigation through both emissions reduction and carbon sequestration, and as the international markets for carbon expand, so sequestered carbon could represent an important new income source for farmers.[42]

Agricultural systems contribute to carbon emissions through the direct use of fossil fuels in farm operations, the indirect use of embodied energy in inputs that are energy-intensive to manufacture and transport, particularly fertilizers and pesticides, and the cultivation of soils resulting in the loss of soil organic matter. Agriculture is also an accumulator of carbon, offsetting losses when organic matter is accumulated in the soil, or when above-ground woody biomass acts either as a permanent sink or is used as an energy source that substitutes for fossil fuels.

Long-term agricultural experiments in both Europe and North America indicate that soil organic matter and soil carbon are lost during intensive cultivation. But both can be increased with sustainable management practices. The greatest dividend comes from conversion of arable to agroforestry as there is a benefit from both increased soil organic matter and the accumulation of above-ground woody biomass. Grasslands within rotations, zero-tillage farming, use of legumes and green manures, and high amendments of straw and manures, also lead to substantial carbon sequestration. There is now good evidence to show that sustainable agricultural systems can lead to the annual accumulation of 300–600kg of carbon per hectare, rising to several tonnes per hectare when trees are intercropped in cropping and grazing systems.

Agriculture as an economic sector also contributes to carbon emissions through the consumption of direct and indirect fossil fuel. With the increased use of nitrogen fertilizers, pumped irrigation and mechanical power, accounting for more than 90 per cent of the total energy inputs to farming, industrialized agriculture has become progressively less energy efficient. The difference between sustainable and conventional systems of production is striking. Low-input or organic rice in Bangladesh, China and Latin America is some 15–25 times more energy efficient than irrigated rice grown in the US. For each tonne of cereal or vegetable from industrialized high-input systems in Europe, 3000–10,000MJ of energy are consumed in its production. But for each tonne of cereal or vegetable from sustainable farming, only 500–1000MJ are consumed.[43]

It is now known that intensive cultivation of cereals leads to reductions in soil organic matter and carbon. But recent years have seen an extraordinary growth in the adoption of 'conservation tillage' and 'zero-tillage' systems, particularly in the

Americas. These systems of cultivation maintain a permanent or semi-permanent organic cover on the soil. The function is to protect the soil physically from the action of sun, rain and wind, and to feed soil biota. The result is reduced soil erosion and improved soil organic matter and carbon content. Zero-tillage systems and those using legumes as green manures and/or cover crops contribute to organic matter and carbon accumulation in the soil. Zero-till systems also have an additional benefit of requiring less fossil fuel for machinery passes. Intensive arable with zero-tillage results in the annual accumulation of 300–600kg of carbon per hectare, but with mixed rotations and cover crops can accumulate up to 1300kg of carbon per hectare.

The 1997 Kyoto Protocol to the UN Framework Convention on Climate Change established an international policy context for the reduction of carbon emissions and expansion in carbon sinks in order to address climate change. Under the protocol and the 2001 Bonn and Marakesh agreement, the principle of financial and technological transfers to land management projects and initiatives was established. Article 17 permits countries to produce certified emissions reductions, also known as offsets, and emissions reductions units through joint implementation projects. As it is cheaper at the margin for many countries to abate greenhouse gas emissions, such working together for joint implementation is in theory a cost-effective mechanism for achieving global targets.

But for real impacts on climate change to occur, sinks must become permanent. If lands under conservation tillage are ploughed, then all the gains in soil carbon and organic matter are lost. This poses a big challenge for trading systems, as there is no such thing as a permanent emissions reduction nor a permanently sequestered tonne of carbon. Despite these uncertainties, carbon banks, 'boards of trade' and trading systems first emerged during the year 2000. The early carbon trading systems set per tonne credit values mostly in the US$2–10 range, though the real value of each tonne sequestered is much higher. The important policy questions centre on how to establish permanent or indefinite sinks, how to prevent leakage, such as reploughing of zero-tilled fields or deforestation, how to agree measurements, and whether the cost of implementation can be justified through their additional side effects or multifunctionality.

We do not yet know how much carbon could be locked up in response to monetary incentives for carbon sequestration. The empirical evidence is relatively sparse, and practical experience even more limited. No agreed system of payment levels has yet been established. Another unresolved issue relates to the location for the greatest carbon returns on investments. Investments in creating sustainable systems in the tropics are likely to be cheaper than in temperate regions, where industrialized agriculture prevails. Such financial transfers from industrialized to developing countries could produce substantial net global benefits as well as benefit poor farmers. At current prices, it is clear that farmers will not become solely carbon farmers. However, systems accumulating carbon are also delivering many other public goods, such as improved biodiversity and clean water from watersheds, and policy makers may also seek to price these so as to increase the total payment package. Carbon, therefore, represents an important new source of income for farmers, as well as helping to encourage them to adopt sustainable practices.

Could Better Policies Help?

These external costs and benefits of agriculture raise important policy questions. In particular, should farmers receive public support for the public benefits they produce in addition to food? Should those that pollute have to pay for restoring the environment and human health? These two principles are called 'the provider gets' and 'the polluter pays', and they are important to both industrialized and developing countries. Three categories of policy instruments are available: advisory and institutional measures, regulatory and legal measures, and economic instruments. In practice, effective pollution control and supply of desired public goods requires a mix of all three approaches, together with integration across sectors.

Advisory and institutional measures have long formed the backbone of policies to internalize costs and so prevent agricultural pollution. These rely on the voluntary actions of farmers, and are favoured by policy makers because they are cheap and adaptable. Advice is commonly given in the form of codes of good agricultural practice, such as recommended rates of application of pesticides and fertilizer, or measures for soil erosion control. Most governments still employ extension agents to work with farmers on technology development and transfer. A variety of institutional mechanisms can also help to increase social capital and the uptake of more sustainable practices, including encouraging farmers to work together in study groups, investing in extension and advisory services to encourage greater interaction between farmers and extensionists, and encouraging new partnerships between farmers and other rural stakeholders, as regular exchanges and reciprocity increase trust and confidence, and lubricate cooperation.

Regulatory and legal measures are also used to internalize external costs. This can be done either by setting emissions standards for the discharge of a pollutant, or by establishing quality standards for the environment receiving the pollutant. Polluters who exceed standards are then subject to penalties. There are many types of standards, such as operating standards to protect workers, production standards to limit levels of contaminants of residues in foods, emissions standards to limit releases or discharges, such as of silage effluents, and environmental quality standards for undesirable pollutants in vulnerable environments, such as pesticides in water. But the problem with such regulations is that most agricultural pollutants are diffuse, or nonpoint, in nature. It is impossible for inspectors to ensure compliance on hundreds of thousands of farms in the way that they can with a small number of factories. Regulations are also used to eliminate certain practices, and include bans on spraying of pesticides close to rivers and on straw-burning in the UK, and the mandatory requirement to complete full nutrient accounts for farms, such as in The Netherlands and Switzerland. A final use for regulations is the designation and legal protection of certain habitats and species, which are set at national or international levels.

Economic instruments can be used either to ensure that the polluter bears the costs of the pollution damage and the abatement costs incurred in controlling the pollution. They can also be used to reward good behaviour. A variety of economic instruments are available for achieving internalization, including environmental taxes and charges, tradable permits and targeted use of public subsidies and incentives. Environmental taxes seek to shift the burden of taxation away from economic 'goods', such as labour, towards environmental 'bads', such as waste and pollution. Clearly the market prices for agricultural inputs do not currently reflect the full costs of their use. Environmental taxes or pollution payments, however, seek to internalize some of these costs, so encouraging individuals and businesses to use them more efficiently. Such taxes offer the opportunity of a 'double dividend' by cutting environmental damage, particularly from nonpoint sources of pollution, whilst promoting welfare. However, many opponents still believe that environmental taxes stifle economic growth, despite compelling evidence to the contrary.[44]

There are now a wide range of environmental taxes used by countries in Europe and North America. These include carbon and energy taxes in Belgium, Denmark and Sweden; chlorofluorocarbon taxes in Denmark and the US; sulphur taxes in Denmark, France, Finland and Sweden; nitrogen oxide charges in France and Sweden; leaded and unleaded petrol differentials in all European Union (EU) countries; landfill taxes in Denmark, The Netherlands and the UK; groundwater extraction charges in The Netherlands; and sewage charges in Spain and Sweden. However, environmental taxes have rarely been applied to agriculture, with the notable exception of pesticide taxes in Denmark, Finland, Sweden and in several states of the US; fertilizer taxes in Austria, Finland, Sweden, and again several states of the US; and manure charges in Belgium and The Netherlands.[45]

The alternative to penalizing farmers through taxation is to encourage them to adopt non-polluting technologies and practices. This can be done by offering direct subsidies for adoption of sustainable technologies, and by removing perverse subsidies that currently encourage polluting activities.[46] An important policy principle suggests that it is more efficient to promote practices that do not damage the environment rather than spending on cleaning up after a problem has been created. Many governments provide some direct or indirect public support to their domestic agricultural and rural sectors. Increasingly, payments are being shifted away from being production-linked, such as through price support or direct payments, to being retargeted to support sustainable practices. Generally, though, only small amounts of total budgets have been put aside for environmental improvements though such policies as the US Conservation Reserve Programme, the EU's agri-environmental and rural development programmes, and the Australian Landcare programme. Many now believe that all public support for farming should be entirely linked to the provision of public environmental and social goods.

The Radical Challenge of Integration

The substantial external costs of modern agriculture, and the known external benefits of sustainable agricultural systems, pose great challenges for policy makers. A range of policy reforms could do much to internalize some of these costs and benefits in prices. In practice, as no single solution is likely to suffice, the key issue rests on how policy makers choose an appropriate mix of solutions, how these are integrated, and how farmers, consumers and other stakeholders are involved in the process of reform itself. Attention will therefore need to be paid to the social and institutional processes that both encourage farmers to work and learn together, and result in integrated cross-sectoral partnerships. Policy integration is vital, yet most policies seeking to link agriculture with more environmentally-sensitive management are still highly fragmented.

The problem is that environmental policies have tended only to green the edges of farming. An essentially modernist agriculture remains much as it ever was, but is now tinged green. Non-crop habitats have been improved, perhaps some hedges, woodlands and wetlands. But the food is largely produced in the conventional manner. The bigger challenge is to find ways of substantially greening the middle of farming – in the field rather than around the edges. A thriving and sustainable agricultural sector requires both integrated action by farmers and communities, and integrated action by policy makers and planners. This implies both horizontal integration with better linkages between sectors, and vertical integration with better linkages from the micro- to macro-level. Most policy initiatives are still piecemeal, affecting only a small part of a individual farmer's practices, and so not necessarily leading to substantial shifts towards sustainability.

The 1990s saw considerable global progress towards the recognition of the need for policies to support sustainable agriculture. In a few countries, this has been translated into supportive and integrated policy frameworks. In most, however, sustainability policies remain at the margins. Only two countries – Cuba and Switzerland, discussed in more detail below – have given explicit national support for sustainable agriculture, putting it at the centre of agricultural development policy. Several countries have given sub-regional support, such as the states of Santa Caterina, Paraná and Rio Grande do Sol in southern Brazil supporting zero-tillage and catchment management, and some states in India supporting watershed management or participatory irrigation management. A much larger number have reformed parts of agricultural policies, such as China's support for integrated ecological demonstration villages, Kenya's catchment approach to soil conservation, Indonesia's ban on pesticides and programme for farmer field schools, India's support for soybean processing and marketing, Bolivia's regional integration of agricultural and rural policies, Sweden's support for organic agriculture, Burkina Faso's land policy, and Sri Lanka and the Philippines' stipulation that water users' groups manage irrigation systems.

One of the best examples of a carefully designed and integrated programme comes from China. In March 1994, the government published a White Paper to set out its plan for implementation of Agenda 21. This put forward ecological farming, known as *Shengtai Nongye* or agroecological engineering, as the approach to achieve sustainability in agriculture. Pilot projects have been established in some 2000 townships and villages spread across 150 counties. Policy for these 'eco-counties' is organized through a cross-ministry partnership, which uses a variety of incentives to encourage adoption of diverse production systems to replace monocultures. These include subsidies and loans, technical assistance, tax exemptions and deductions, security of land tenure, marketing services and linkages to research organizations. These eco-counties contain some 12 million hectares of land, about half of which is cropland, and though only covering a relatively small part of China's total agricultural land, do illustrate what is possible when policy is coordinated and holistic.

An even larger set of countries has seen some progress on agricultural sustainability at project and programme level. However, progress occurs despite, rather than because of, explicit policy support. No agriculture minister is likely to say they are against sustainable agriculture, yet good words remain to be translated into comprehensive policy reforms. Sustainable agricultural systems can be economically, environmentally and socially viable, and at the same time contribute positively to local livelihoods. But without appropriate policy support, they are likely to remain at best localized in extent, and at worst simply wither away. In Europe and North America, most policy analysts and sustainable agriculture organizations now agree that a policy framework that integrates support for farming together with rural development and the environment could create new jobs, protect and improve natural resources, and support rural communities. Such a policy could have many of the elements of the progressive Swiss and Cuban policy reforms made during the 1990s.

Cuba's National Policy for Sustainable Agriculture

At the turn of the century, Cuba was the only developing country with an explicit national policy for sustainable agriculture. To the end of the 1980s, Cuba's agricultural sector was heavily subsidized by the Soviet bloc. It imported more than half of all calories consumed, and 80–95 per cent of wheat, beans, fertilizer, pesticides and animal feed. It received three times the world price for its sugar. At the time, Cuba had the most scientists per head of population in Latin America, the most tractors per hectare, the second highest grain yields, the lowest infant mortality, the highest number of doctors per head population and the highest secondary school enrolment. But in 1990, trade with the Soviet bloc collapsed, leading to severe shortages in all imports, and restricting farmers' access to petroleum, fertilizers and pesticides.

The government's response was to declare an 'Alternative Model' as the official policy – an agriculture that focuses on technologies that substitute local knowledge, skills and resources for the imported inputs. It also emphasizes the diversification of agriculture, oxen to replace tractors, Integrated Pest Management to replace pesticides, and the promotion of better cooperation among farmers both within and between communities. It has taken time to succeed. Calorific availability was 2600 kilocalories per day in 1990, fell disastrously to between 1000–1500 kilocalories per day soon after the transition, leading to severe hunger, but subsequently rose to 2700 kilocalories per day by the end of the 1990s.

Two important strands to sustainable agriculture in Cuba have emerged. First intensive organic gardens have been developed in urban areas – self-provisioning gardens in schools and workplaces (*autoconsumos*), raised container-bed gardens (*organoponicos*) and intensive community gardens (*huertos intensivos*). There are now more than 7000 urban gardens, and productivity has grown from 1½kg per square metre to nearly 20kg per square metre. Second, sustainable agriculture is encouraged in rural areas, where the impact of the new policy has already been remarkable. More than 200 village-based and artisanal Centres for the Reproduction of Entomophages and Entomopathogens have been set up for biopesticide manufacture. Each year, they produce 1300 tonnes of *B.t.* sprays for lepidoptera control, nearly 800 tonnes of *Beaveria* sprays for beetle control, 200 tonnes of *Verticillium* for whitefly control and 2800 tonnes of *Trichoderma*, a natural enemy. Many biological control methods are proving more efficient than pesticides. Cut banana stems baited with honey to attract ants are placed in sweet potato fields, and have led to control of the sweet potato weevil. There are 170 vermicompost centres, the annual production of which has grown from 3 to 93 thousand tonnes. Crop rotations, green manuring, intercropping and soil conservation have all been incorporated into polyculture farming.

At the forefront of the transition towards sustainable agriculture has been the Grupo de Agricultura Organica, formerly known as the Asociación Cubanes Agricultural Organica, formed in 1993. GAO brings together farmers, field managers, field experts, researchers and government officials to help spread the idea that organic-based alternatives can produce sufficient food for Cubans. Despite great progress, there remain many difficulties, including proving the success of the alternative system to sceptical farmers, scientists and policy makers, developing new technologies sufficiently quickly to meet emergent problems, coordinating the many actors to work together, the need for continued decentralization of decision making to farmer level, and the appropriate land reform to encourage investment in natural asset-building.[47]

The Swiss National Policy for Sustainable Agriculture

The Swiss Federal Agricultural Law was revised in 1992 to target subsidies towards ecological practices, and then radically amended in 1996 following a national referendum in which 78 per cent of the public voted in favour of change.[48] The main priority was maintaining important positive side effects of upland livestock farming – in particular open meadows for skiing pistes in winter, but also maintenance of rural mountain communities that are at the root of Swiss culture. Policy now differentiates between three different levels of public support. Tier one provides support for specific biotypes, such as extensive grassland and meadows, high-stem fruit trees and hedges. Tier two supports integrated production with reduced inputs, meeting higher ecological standards than conventional farming, and Tier three provides the most support for organic farming. As the directors of the federal agricultural and environmental offices, Hans Berger and Philippe Roch, have said, 'in ecological terms, Swiss agriculture is on the road to sustainability. There are encouraging signs that the agricultural reform has already began to have positive effects on nature and the environment.'

Farmers must meet several minimum conditions to receive payments for integrated production, the so-called 'ecological standard' of performance. They must provide evidence that nutrient use matches crop demands, with livestock farmers having to sell surplus manures or reduce livestock numbers. Soils must be protected from erosion, and erosive crops, such as maize, can only be cultivated if alternated in rotation with meadows and green manures. At least 7 per cent of the farm must be allocated for species diversity protection through so-called ecological compensation areas, such as unfertilized meadows, hedgerows and orchards. Finally, pesticide use is restricted. A vital element of the policy process is that responsibility to set, administer and monitor is devolved to cantons, farmers' unions and farm advisors, local bodies and non-government organizations. By the end of the 1990s, 85 per cent of farmland complied with the basic ecological standard, which allows farmers to receive public subsidies. Some 5000 farms are now organic, and all farmers are soon expected to meet the 'ecological standard'. Pesticide applications have fallen by a third in a decade, phosphate use is down by 60 per cent and nitrogen use by half. The land under semi-natural habitats has expanded during the decade, from 1 to 6 per cent in the plains, and from 7 to 23 per cent in the mountains.

There is much to learn from these experiences of Switzerland and Cuba, as these remain the only two countries at the turn of the century who had put sustainable agriculture at the centre of their national policy. It is also true that Switzerland is wealthy and can afford these new payments to farmers for extra services, and that Cuba had no choice – it could not afford to do anything else. It is difficult to draw wide conclusions from these two cases. However, as American farmer and poet Wendell Berry has put it about his own country, 'I cannot see why a healthful, dependable, ecologically sound farm- and farmer-conserving agricultural economy is not a primary goal of this country.' Is there the political will in all the remaining 200 or so countries? The options are available, and the net benefits would be substantial. To date, the words have been easy, but the practice much more difficult.

Concluding comments

In this chapter, I have adopted a fairly narrow economic perspective to set out some of the real costs of modern agricultural and food systems. The side effects, or externalities, of food production systems are substantial, yet these do not appear in the price of food. The costs of lost biodiversity, water pollution, soil degradation and ill health in humans are shifted elsewhere in economies and, because they are difficult to identify and measure, they are easily lost. Allocating monetary values to these externalities is only one part of the picture, as these methods are inevitably inexact, but they do illustrate the size of the problem. The term multifunctional, when applied to agriculture, implies a system that does more than just produce food. Agriculture shapes landscapes, water quality, biodiversity and carbon stocks in soils. All of these are important public goods, and represent new income opportunities for farmers. But progress is slow, as policy reforms have lagged behind. There is a need for radical integration of policies to support transitions towards agricultural systems that minimize their external costs and maximize their positive side-effects.

Notes

1 On the cheapness of food, Donald Worster recognized this about a decade ago: 'the farm experts merely assume, on the basis of marketplace behaviour, that the public wants cheapness above all else. Cheapness, of course, is supposed to require abundance, and abundance is supposed to come from greater economies of scale, more concentrated economic organisation, and more industrialised methods. The entire basis for that assumption collapses if the marketplace is a poor or imperfect reflector of what people want' (Worster, 1993, p87).

2 See Astor and Rowntree (1945, p33, p47).

3 For more on George Stapledon, see Conford, 1988, pp192–193, pp196–197.

4 Despite my regular use of these five terms as capitals, I agree with the misgivings that many have. Capital implies an asset, and assets should be looked after, protected and built up. But as a term, capital is problematic for two reasons. It implies measurability and transferability. Because the value of something can be assigned a single monetary value, then it appears to matter not if it is lost, as we could simply allocate the required money to buy another, or transfer it from elsewhere. But we know this must be nonsense. Nature, and its cultural and social meanings, is not so easily replaceable. It is not a commodity, reducible only to monetary values. Nonetheless, as terms, natural capital and social capital have the uses in helping to reshape thinking around basic questions such as what is agriculture for, and what system works best? For further discussions, see Benton, 1998; Bourdieu, 1986; Coleman, 1988, 1990; Putnam, 1995; Costanza et al, 1997 and 1999; Carney, 1998; Flora, 1998; Grootaert, 1998; Ostrom, 1998; Pretty, 1998; Scoones, 1998; Uphoff, 1998; Pretty and Ward, 2001.

5 Worster, 1993, p92. See also Michael Neuman of Texas A&M University, who resolves the concept of sustainability into four very simple and compelling ideas: the rates of consumption, rates of production, rates of accumulation and depletion, and rates of assimilation.

6 See Pretty, 1998; FAO, 1999; Conway and Pretty, 1991; Altieri, 1995; Pingali and Roger, 1995; Conway, 1997.

7 For more on sustainable agriculture definitions and principles, see Altieri, 1995, 1999; Thrupp, 1996; Conway, 1997; Pretty, 1995a, 1998; Drinkwater et al, 1998; Tilman, 1998; Hinchliffe et al, 1999; Zhu et al, 2000; Wolfe, 2000.

8 An externality is any action that affects the welfare of or opportunities available to an individual or group without direct payment or compensation, and may be positive or negative. See Baumol and Oates, 1988; Pearce and Turner, 1990; EEA, 1998; Brouwer, 1999; Pretty et al, 2000. Economists distinguish between 'technological' or physical externalities, and 'pecuniary', or price effect, externalities. Pecuniary externalities arise, for example, when individuals or firms purchase or sell large enough quantities of a good or service to affect price levels. The change in price levels affects people who are not directly involved in the original transactions, but who now face higher or lower prices as a result of those original transactions. These pecuniary externalities help some groups and hurt others, but they do not necessarily constitute a 'failure' of the market economy. An example of a pecuniary externality is the rising cost of housing for local people in rural villages that results from higher-income workers from metropolitan areas moving away from urban cores and bidding up the price of housing in those villages. Pecuniary externalities are a legitimate public concern, and may merit a public policy response. Technological externalities, however, do constitute a form of 'market failure'. Dumping pesticides sewage into a lake, without payment by the polluter to those who are adversely affected, is a classic example of a technological externality. The market 'fails' in this instance, because more pollution occurs than would be the case if the market or other institutions caused the polluter to bear the full costs of its actions. It is technological externalities that are commonly simply termed 'externalities' in most environmental literature (see Davis and Kamien, 1972; Common, 1995; Knutson et al, 1998).

9 For more on the value of nature's goods and services, see Abramovitz, 1997; Costanza et al, 1997 and 1999; Daily, 1997; and the whole issue of *Ecological Economics*, 1999, volume 25, issue 1.

10 See Pimentel et al, 1992, 1995; Rola and Pingali, 1993; Pingali and Roger, 1995; Evans, 1995; Steiner et al, 1995; Fleischer and Waibel, 1998; Waibel and Fleischer, 1998; Bailey et al, 1999; Norse et al, 2000. The data from these studies are not easily comparable in their original form as different frameworks and methods of assessment have been used. Methodological concerns have also been raised about some studies. Some have noted that several effects could not be assessed in monetary terms, whilst others have appeared to be more arbitrary (e.g. the $2 billion cost of bird deaths in the US is arrived at by multiplying 67 million losses by $30 a bird: see Pimentel et al, 1992). The Davison et al (1996) study on Netherlands agriculture was even more arbitrary. It added an estimate of the costs farmers would incur to reach stated policy objectives, and these were based on predicted yield reductions of 10–25% arising from neither cheap nor preferable technologies, which led to a large overestimate of environmental damage (see Bowles and Webster, 1995; Crosson, 1995; Pearce and Tinch, 1998; van der Bijl and Bleumink, 1997).

11 On the effects of pesticides in rice, see Rola and Pingali, 1993; Pingali and Roger, 1995.

12 Hartridge and Pearce, 2001.

13 See Pretty et al, 2000, 2001. These are likely to be conservative estimates of the real costs. Some costs are known to be substantial underestimates, such as acute and chronic pesticide poisoning of humans, monitoring costs, eutrophication of reservoirs and restoration of all hedgerow losses. Some currently cannot be calculated, such as dredging to maintain navigable water, flood defences, marine eutrophication and poisoning of domestic pets. The costs of returning the environment or human health to pristine conditions were not calculated, and treatment and prevention costs may be underestimates of how much people might be willing to pay to see positive externalities created. The data also do not account for time lags between the cause of a problem and its expression as a cost, as some processes long since stopped may still be causing costs; some current practices may not yet have caused costs, and this study did not include the externalities arising from transporting food from farms to manufacturers, processors, retailers and finally to consumers.

14 See Pretty et al, 2001.

15 The government's Office of the Director General of Water Services sets industry price levels each 5 years, which determine both the maximum levels of water bills and specifies investments in water quality treatment. During the 1990s, the water industry undertook pesticide and nitrate removal schemes, resulting in the construction of 120 plants for pesticide removal and 30 for nitrate removal (Ofwat, 1998). Ofwat estimates that water companies will spend a further £600 million between 2000 and 2005 on capital expenditure alone due to continuing deterioration of 'raw water' quality due to all factors. Ofwat predicts capital expenditure for pesticides to fall to £88 million per year at the end of the 1990s/early 2000s; and for nitrate to fall to £8.3 m/yr. Although Ofwat has sought to standardize reporting, individual companies report water treatment costs in different ways. Most do distinguish treatment for pesticides, nitrate, *Cryptosporidium* and several metals (iron, manganese and lead). The remaining treatment costs for phosphorus, soil removal, arsenic and other metals, appear under a category labeled 'other'. Of the 28 water companies in England and Wales, three report no expenditure on treatment whatsoever; and a further three do not disaggregate treatment costs, with all appearing under 'other'. Twenty companies report expenditure on removal of pesticides, 11 on nitrates, and 10 on *Cryptosporidium*. It is impossible to tell from the records whether a stated zero expenditure is actually zero, or whether this has been placed in the 'other' category. Using Ofwat and water companies' returns, we estimate that 50% of expenditure under the 'other' category refers to removal of agriculturally-related materials.

16 We originally calculated the annual external costs of these gases to be £280 million for methane, £738 million for nitrous oxide, £47 million for carbon dioxide and £48 million for ammonia. But a more appropriate measure would have been to use an accepted policy target for these costs, such as the 25% cut required to meet agreements made in the Kyoto Protocol. This would put the total annual costs at £314 million.

17 DETR, 1998a, 1998b; Pretty, 1998; Campbell et al, 1997; Pain and Pienkowski, 1997; Mason, 1998; Siriwardena et al, 1998; Krebs et al, 1999.

18 Repetto and Baliga, 1996; Pearce and Tinch, 1998; HSE, 1998a, 1998b; Pretty, 1998.

19 Fatalities from pesticides at work in Europe and North America are rare – one a decade in the UK, and eight a decade in California. In the UK, a variety of institutions collect mortality and morbidity data, but in California, where there is the most comprehensive reporting system in the world, official records show that 1200–2000 farmers, farmworkers and the general public are poisoned each year (see CDFA, passim; Pretty, 1998). There appears to be greater risk from pesticides in the home and garden where children are most likely to suffer. In Britain, 600–1000 people need hospital treatment each year from home poisoning.

20 On food poisoning in the UK, see PHL, 1999; Evans et al, 1998; Wall et al, 1996. For a study of foodborne illnesses in Sweden, see Lindqvist et al, 2001. When BSE was first identified in late 1986, research confirmed that it was a member of a group of transmissible diseases occurring in animals and humans. It appeared simultaneously in several places in the UK, and has since occurred in native born cattle in other countries. By mid-2001, more than 180,000 cases had been confirmed in the UK, the epidemic having reached a peak in 1992. The link between bovine spongiform encephalopathy (BSE) and variant Creutzfeldt-Jakob Disease (CJD) in humans was confirmed in 1996, and 100 deaths from CJD have occurred to 2001. The annual external costs of BSE were £600 million at the end of the 1990s. See NAO, 1998; WHO, 2001. By mid-2001, there had been 181,000 cases of BSE reported in the UK, 648 in Ireland, 564 in Portugal, 381 in Switzerland, 323 in France, 81 in Germany, 46 in Spain and 34 in Belgium. For more on the important lessons of BSE, see Lobstein et al, 2001; Millstone and van Zwanenberg, 2001.

21 For an excellent review of food crises and the need for new thinking in food systems, see Lang et al, 2001. Also see Waltner-Toews and Lang, 2000.

22 Donald Worster (1993, p18) points out that this was not, of course, the end of the story. Control through the levees did not stop conflicts between farmers wanting water for irrigation, and others wanting to provide waterfowl with a habitat. Nor did they stop pesticides and nutrients running

off the fields. Nor did they stop the emergence livestock feedlots with their massive production of animal wastes.

23 On the effects of changes in the German landscape on flooding, see van der Ploeg et al, 1999, 2000. Vo-Tong Xuan, Rector of Angiang University in Vietnam notes similar problems in the Mekong Delta, where farmers have switched from one crop of floating rice per year to three short duration crops of modern varieties, which has led to an occurrence of floods on an annual basis.

24 On the effects of landscape, in particular paddy rice, on water control in Japan, see Minami et al, 1998; Kato et al, 1997; OECD, 2000.

25 On the externalities of Chinese agriculture, see Cai et al, 1999; Norse et al, 2000.

26 FAO, 2000.

27 On the values of wetlands, see Heimlich et al, 1998. For a study of eutrophication costs, see Pretty et al, 2001a, *A Preliminary Assessment of the Environmental Damage Costs of Eutrophication of Fresh Waters in England and Wales*. See also Postel and Carpenter, 1997 Ewel, 1997. For a study showing that the costs of creating wetlands is less than for constructing treatment plants, see Gren, 1995.

28 See Keeny and Muller, 2000.

29 We distinguished between value-loss costs arising from the reduced value of clean or non-eutrophic (nutrient-enriched) water, and the direct costs incurred in responding to eutrophication plus the costs of changing behaviour and practices to meet legal obligations. Value-loss costs, by definition, represent a loss of existing value, rather than an increase in costs, and are divided into two categories: use values and non-use values. Use values are associated with private benefits gained from actual use (or consumption) of ecosystem services, and can include private sector uses (e.g. agriculture, industry), recreation benefits (e.g. fishing, water sports, bird watching), education benefits, and general amenity benefits. Non-use values are of three types: option values, bequest values and existence values. See Pretty et al, 2001; also Mason, 1996; Environment Agency, 1998.

30 Total fertilizer consumption (N, P and K) for the world was 138 million tonnes in the year 2000, comprising 83mt of nitrogen, 32mt of phosphate, and 22mt of potassium. Nitrogen consumption in western Europe was 17mt, in North America 21mt, in South Asia 21mt, in the Russian states 38mt and in China 38mt. World consumption of all fertilizer has grown from 30mt in 1960 (when nitrogen consumption was 11mt, phosphate 11mt and potassium 8mt). Data from the International Fertilizer Industry Association, Paris.

3

External Costs of Agricultural Production in the United States

Erin M. Tegtmeier and Michael D. Duffy

Introduction

All agricultural practices impact the environment. Industrial agriculture is increasingly being recognized for its negative consequences on the environment, public health and rural communities. Soil loss and erosion reduce crop yields and impair natural and manmade water systems (Atwood, 1994; Clark et al, 1985; Crosson, 1986; Evans, 1996; Holmes, 1988; Pimentel et al, 1995). Runoff of agricultural chemicals from farm fields contaminates groundwater and disrupts aquatic ecosystems (Conway and Pretty, 1991; Pimentel et al, 1992; Pretty et al, 2003; USDA, 2000d; Waibel and Fleischer, 1998). Monocropping and feedlot livestock production threaten diversity and may increase foodborne pathogens and antibiotic resistance in humans, as well as pest resistance to chemical controls (Altieri, 1995; Iowa State University and The University of Iowa Study Group, 2002; National Research Council, 1989). The health of rural communities is affected negatively by declining community involvement and increased division of social classes (Bollman and Bryden, 1997; Flora et al, 2002).

The costs of impacts are external to agricultural systems and markets for products. They are borne by society at large. Assessing the monetary costs of such impacts aids in fully identifying their consequences. Cost estimates can inform and guide policy makers, researchers, consumers and agricultural producers and may encourage a closer look at the impacts of industrial agriculture.

According to Western neoclassical economics, well-defined property rights ensure that an owner benefits exclusively from use of property and wholly incurs the costs of use. However, in many circumstances, costs are borne by those who are not decision makers. Impacts of agriculture involve costs to individuals and communities who are not making decisions about production methods. These consequences indicate when property rights are not well defined and they represent

Reprinted from Tegtmeier E and Duffy A. 2004. The external costs of agricultural production in the United States. *Int. J. Agric. Sust.* 2(1), 155–175, Earthscan, London.

market failures, which lead to economic inefficiencies. In an unregulated situation, a polluter will weigh the private costs and benefits of an action, producing too much pollution with too little cleanup or producing too much product at too low a price (Miranowski and Carlson, 1993; Samuelson and Nordhaus, 1995).

Because these effects occur outside the marketplace, they are called externalities. 'Negative' externalities occur when costs are imposed; 'positive' externalities occur when others gain benefits without charge. To identify forces resulting in externalities and actions that may mitigate their effects, economists distinguish types of externalities. They can be broadly classified by the nature of their consumption (public *vs* private) and by their effects on resource allocation (pecuniary *vs* technological).

An externality is 'consumed' by those affected by it. Many externalities have the characteristic of a public good (or bad) where consumption by one individual does not reduce the good's availability to others nor the utility of consumption received by others (Baumol and Oates, 1988). For example, polluted air or scenic views are experienced in this way. They are public and undepletable and are not exchanged in the marketplace where each consumer can be charged for use. A private externality, however, is depletable. If an individual dumps trash onto another's property, this affects only the victim (Baumol and Oates, 1988). Externalities that affect public goods are of greater policy interest because there are fewer 'defensive activities' available to victims.

Externalities also are differentiated by whether the competitive marketplace can adjust to their effects. In the context of agriculture, soil erosion is a technological externality, whereas the decline of rural communities as a consequence of the character and structure of large, industrial farms is considered pecuniary. Research has described declines in purchases from local businesses, increases in crime and civil court cases and decreased property values (Flora et al, 2002). These effects, although undesirable, are not results of market failure in the neoclassical sense. They are, rather, results of the market responding to changes in supply and demand.

Economists and policy makers rely on valuation, or the process of assigning economic value, to apply the concept of externalities. A monetary metric provides a base for comparisons to aid in policy decisions. Externalities, however, often are highly complex and difficult to delineate. Even though assumptions are necessary, economists continue to refine techniques and view valuation as a way of revealing problems with the status quo.

A key assumption underlying valuation is that economic value of an object or service is derived through a function that contributes to human well-being and can be measured by 'establishing the link between that function and some service flow valued by people' (Freeman, 1998, p305). Measurement is based on the concepts of willingness to pay (WTP) for the improvement of an object or service or willingness to accept compensation (WTAC) for its deterioration (Farber et al, 2002; Hanley et al, 1997). Valuation approaches generally fall into two categories: direct survey methods and indirect methods (Hanley et al, 1997; Zilberman and Marra, 1993). Survey techniques seek to measure individual preferences for improvement in a situation or loss of well-being associated with a condition. Indirect valuation methods observe behaviour in related markets and use such data as proxies.

In all valuation efforts, sufficient and reliable data are a concern. People who are surveyed often do not have well-defined preferences to which they can assign value or they simply may not be familiar with the services provided by an environmental resource (Hanley et al, 1997). Also, value for many resources is composed of both use values and non-use values that may be particularly difficult to delineate (Hanley et al, 1997). Non-use values include existence value (the value of knowing a thing merely exists, regardless of intent to use) and option value (the value of preserving a resource for possible future use).

We continue to learn about the intricacies of ecosystems on a societal level, but critical data that would strengthen current indirect valuation projects often are not available. Also, environmental externalities, especially those associated with agriculture, frequently have broad spatial and temporal effects, adding to the complexity of valuation efforts.

Study Framework

This study assembles available valuation data to arrive at an aggregate, national figure for particular external costs of agricultural production in the US. We focus on technological externalities with public goods characteristics. A literature review revealed data on such externalities in three broad damage categories:

- natural resources (composed of water, soil and air subcategories);
- wildlife and ecosystem biodiversity;
- human health (composed of pathogen and pesticide subcategories).

A study on the total external costs of agriculture in the UK (Pretty et al, 2000) guided our work. Pretty et al compiled data from various datasets and studies to estimate costs, categorized by damages to natural capital and human health. They calculated costs of £208 per hectare of arable land and permanent pasture. This figure is higher than the cost per cropland hectare for the US reported here. The difference, in part, may be due to the inclusion of costs of the BSE (bovine spongiform encephalopathy or 'mad cow') crisis and the difference in agricultural land area. Also, the UK study included costs to public agencies for monitoring and administering environmental and public health programmes associated with agriculture.

We collected programme costs in the form of agency budgets, but decided not to incorporate them into our total cost figure. This is not meant to diminish the research and conclusions of Pretty et al. But, considering the available data for direct costs, we feel that using programme costs as proxies could be viewed as double counting. And, as Pretty et al acknowledge, such activities may be necessary for any type of agricultural production. However, programme costs would likely decrease if agriculture were more environmentally benign.

Other studies on agricultural cost accounting in the UK include Adger and Whitby (1991, 1993) and Hartridge and Pearce (2001). Estimates can be found for other European countries as well: Denmark (Schou, 1996), France (Bonnieux et al, 1998; le Goffe, 2000; Piot-Lepetit et al, 1997) and Italy (Tiezzi, 1999). A discussion on integrating agricultural externalities for a number of countries in the EU can be found in Brouwer (1999).

For the US, work has been done by Faeth and Repetto (1991), Hrubovcak et al (2000), Smith (1992) and Steiner et al (1995). The study by Steiner et al is the most comparable to our research in that it compiles available data on national estimates of agricultural externalities. Our analysis relies on some of the same sources, indicating how the lack of current, available data limits investigation. Steiner et al (1995, p210) also acknowledge that external costs ideally should be calculated on a 'location-specific basis – which currently is impossible because of a lack of information'. We subsequently have found a dearth of local or regional data to qualify the national figures.

Steiner et al focused on externalities caused by pesticides, fertilisers and soil erosion and included regulatory programme costs. As reported in 1987–1990 dollars, these costs total \$1.3–3.6 billion, \$12–33 million and \$5.8–20.3 billion, respectively. In effect, we update their study and add information on the treatment of surface water for microbial pathogens, human health costs caused by foodborne pathogens and greenhouse gas emissions. We also attempt to identify, within the scope of the damage categories, a total cost figure attributable to agriculture and a cost figure per cropland hectare.

Methods

Previous studies that assign values to specific impacts of agriculture in the US form the basis of our analysis. Cost estimates are revised and updated to reflect changes in conditions and the Consumer Price Index. Final figures are in 2002 dollars.

Two points in the methodology call for further clarification. We used the Consumer Price Index as opposed to one of the other indices available because we felt that the impact of externalities would be more directly felt by consumers than producers. A second point concerns the changes in technology or production practices that may have occurred since the original estimates were made. In our calculations of damages due to soil erosion, we deflate some of the estimates by a multiplier to address the subsequent decrease in soil erosion. However, this methodology does not fully account for the changes. There really is not a clean way to make such adjustments. This issue points to the need for more updated estimates.

Cost estimates are classified according to production type (crop or livestock) and area-based external cost figures for crop production are also calculated. Agricultural land use areas reported by the US Department of Agriculture (USDA, 2000b) are used. Of 184.1 million hectares of cropland in the US, approximately

15.3 million are idled each year. The remaining 168.8 million hectares is used for area-based calculations. The external cost of crop production within each damage category is divided by 168.8 million hectares to arrive at cost per hectare figures. Area-based figures are not calculated for those external costs associated with livestock production, considering that production practices and the land areas they affect vary greatly and depend on the animal being raised.

Table 3.1 presents our resulting national tally. Table 3.2 summarizes programme budgets of agencies associated with agricultural activities. Following the tables, each damage category is further described with calculation details.

Results

(1) Damage to water resources

Impacts on water resources are gauged by the costs of treatment necessary to control major pollutants associated with agricultural production (microbial pathogens, nitrate and pesticides).

(1a) Treatment for microbial pathogens

Microorganisms in livestock waste can cause several diseases and human health problems. *Cryptosporidium* and *Giardia* are waterborne, disease-causing parasites (USDA, 2000e). They are found in beef herds and *Cryptosporidium* may be prevalent among dairy operations (Juranek, 1995; USDA, 1994, 2000d). *Cryptosporidium* oocysts have been found in 67–97 per cent of surface water sampled in the US according to the Centers for Disease Control and Prevention (CDC, 1996).

The Interim Enhanced Surface Water Treatment Rule is one of the EPA's latest rulings on microbial protection addressing *Cryptosporidium* and continuing requirements for *Giardia* and viruses. According to the EPA's Office of Water, the total annualized national cost for implementing this rule is $307 million (USEPA, 1998a). There are three potential sources of both *Giardia* and *Cryptosporidium*: wildlife, domestic livestock and humans (Pell, 1997). From this, we assume that livestock causes one-third, or approximately 35 per cent, of the damages associated with these pathogens. Applying 35 per cent to $307 million, $107.5 million of the national cost to meet the ruling may be due to livestock production. Updated from 1998 to 2002 dollars, the cost is $118.6 million.

(1b) Treatment for nitrate

Nitrate, a compound of nitrogen, can leach into groundwater sources or be carried by soil particles into surface waters via runoff. Agricultural sources of nitrate include fertilizers, livestock waste and mineralization of crop residues. Agricultural regions have been shown to be highly vulnerable to nitrate contamination of surface and groundwater (USDA, 2000d). Nitrate impairs aquatic ecosystems and is

[a] Contact authors for calculation information on programme costs.
[b] C/L, refers to production type that is main cause of impact: crop, livestock or both.

a human health concern. It can be converted to nitrite in the gastrointestinal tract and may prevent the proper transport of oxygen in the bloodstream, causing methemoglobinaemia, or 'blue-baby syndrome' in infants (USDA, 2000d).

Human activities have doubled the amount of nitrogen in our ecosystems since the 1970s through atmospheric deposition of nitrogen compounds (USEPA, 2002b). Fossil fuel combustion is the primary source of nitrogen oxides (NO_x). Transportation-related sources (engines in vehicles) account for 53 per cent of these emissions, totalling 10–11 million tonnes of NO_x, and large, stationary utility and industrial boilers account for 45 per cent (USEPA, 2002b). Emissions of ammonia (NH_3) from livestock and fertilized croplands contribute to atmospheric deposition of ammonium (NH_4) (Vitousek et al, 1997, as cited in Lawrence et al, 1999). Because ammonium is highly water-soluble, it tends to be deposited closer to emission sources than nitrogen oxides.

The EPA estimated, in 1995 dollars, a total investment of $200 million was needed immediately for water treatment facilities to meet federal nitrate standards. Also, an estimated $3.3 billion is needed over 20 years to replace and maintain water system infrastructure to meet surface water, coliform and nitrate standards (USEPA, 1997a). Considering the additional cost for infrastructure maintenance, we use $200 million as an annual cost. Pretty et al estimated that 80 per cent of nitrate pollution is due to agriculture. We apply this same percentage to $200 million. In 2002 dollars, the facilities cost is $188.9 million per year.

For comparison, Crutchfield et al (1997) employed WTP survey methods to estimate the value placed on reducing nitrates in drinking water for households in four regions in the US. Estimates were $314–351 million per year.

Water treatment costs for nitrate are associated mostly with background levels of inorganic nitrogen from fertilizers. Catastrophic manure spills occur intermittently and are not considered here. Many farmers, but not all who should, appropriately credit nitrogen applied to cropland via manure.

(1c) Treatment for pesticides

Pesticides from agriculture enter surface and groundwater systems through runoff and leachate and pose risks to aquatic and human health. Approximately 447 million kilograms of active ingredients from pesticides are currently used in crop production in the US (Gianessi and Marcelli, 2000) and a number of studies have detected pesticides in water supplies (USDA, 2000d).

The EPA estimated a total need of $400 million, in 1995 dollars, for treatment facilities to meet Safe Drinking Water Act (SDWA) regulations for pesticides and other chemicals (USEPA, 1997a). Approximately 30 per cent of the chemicals listed are pesticides (USEPA, 1998b). Also, agriculture's share of national, conventional pesticide usage is 79 per cent (USEPA, 1999a). So, the $400 million figure is revised using multipliers of 30 per cent and 79 per cent. Updated to 2002 dollars, the annual cost is $111.9 million. This figure does not account for many unregulated pesticides.

Category 1 summary

Total damage to water resources due to agricultural production, according to available research, is calculated to be $419.4 million per year. Crop or livestock production is associated with these costs as follows:

- Livestock – treatment for microbial pathogens ($118.6 million);
- Crop – infrastructure needs for treatment of nitrate and pesticides ($300.8 million).

Using the above cost totals and 168.8 million hectares of cropland, water resources are impacted by cropland at a level of $1.78 per hectare annually.

This is not a complete review of all impacts on water by agricultural production. Of note, the multifaceted impacts of agricultural chemicals and sedimentation on aquatic ecosystems are not included here. The next subsection on soil resources addresses effects of sedimentation on water treatment, storage and conveyance systems. Valuation also is included for fish kills due to pesticides in Subsection 4. However, these do not fully address structural disturbances to habitats and the food chain of aquatic environments.

(2) Damage to soil resources

Agriculture practices result in soil erosion through tillage, cultivation and land left bare after harvest. After such disturbances, wind and water carry soil particles off the land. In 1997, average annual soil erosion due to water from cropland and land in the Conservation Reserve Program (CRP) was 969 million tonnes, with approximately 958 million tonnes coming off cropland. Erosion due to wind in that same year was 762 million tonnes (USDA, 2000c). Conservation efforts since 1982 have reduced soil erosion by 38 per cent on cropland and CRP land combined (USDA, 2001b), with the composition of the combined land use changing as cropland has been enrolled in the CRP. Still, agriculture remains the single largest contributor to soil erosion. To date, external costs of waterborne erosion have been studied and quantified more than those of windborne erosion. Thus, the costs that follow reflect damages due to waterborne erosion only. Because soil erosion greatly affects the condition and use of surface waters, the following costs support the need for integrated land and water policies.

Erosion reduces soil fertility, organic matter and water-holding capacity and negatively affects productivity. Environmental externalities may result with increases of fertilizer and pesticide use to counteract these effects. On-farm costs of lost productivity due to soil erosion are not included here, assuming the majority of these costs are borne by the producer. Although this is not entirely true, it is beyond the scope of this study to identify on-site effects that have off-site impacts. Some estimates of annual on-farm costs due to soil loss include $500–600 million (Crosson, 1986), $500 million to $1.2 billion (Colacicco et al, 1989) and $27 billion (Pimentel et al, 1995).

(2a) Cost to water industry

Sediment causes turbidity in water supplies and transports toxic materials, including fertilizer and pesticide residues that are bound to clay and silt particles. According to Holmes (1988), sediment contributes 88 per cent of total nitrogen and 86 per cent of total phosphorus to the nation's waterways.

Annual costs of supplying water are based on Holmes' method, using a range of treatment costs multiplied by national surface water withdrawals. Updated to 2002 dollars, Holmes' treatment costs are $26.38–78.22 per million litres. Similarly, the EPA's Office of Water (2001c) claims that the cost to treat and deliver drinking water is approximately $527.8 per million litres, 15 per cent of which goes to treatment. According to these figures, treatment costs $79.17 per million litres.

In 1995, water withdrawn for public supply was estimated at 152.174 billion litres per day, of which 63 per cent (approximately 95.87 billion litres per day) was from surface water sources (USGS, 1998).

Holmes (1988) estimated that cropland contributes 30 per cent of total suspended solids. Therefore, costs attributed to agriculture are calculated using 30 per cent of the estimate of 95.87 billion litres per day at a cost of $26.38–79.17 per million litres. Our numbers, $277–831.1 million, are likely to be conservative because treatment of groundwater sources and erosion from pastureland are not considered. However, there may be some overlap between these costs and those to meet nitrate water standards as discussed previously.

(2b) Lost capacity of reservoirs

Reservoir capacity lost to sedimentation poses a complex problem. Many existing reservoirs are irreplaceable because of unique site characteristics. Dredging is almost prohibitively expensive at a minimum cost of $2.50 per cubic metre. Additionally, there are few disposal sites for dredged material. Alternative energy sources may partially alleviate the need for reservoirs for energy production, but, in terms of water storage, the problem remains (Morris and Fan, 1998).

Although building new reservoirs may not be the realistic solution, this impact is calculated in terms of construction costs to provide some valuation of the problem. Crowder's model (1987) for assessing the cost of reservoir sedimentation is updated.

Total national water storage capacity is 627.6 billion cubic metres (Graf, 1993; Morris and Fan, 1998). Crowder (1987) reported that 0.22 per cent of the nation's water storage capacity is lost annually. Atwood (1994, as cited in USDA, 1995) examined survey records of reservoirs and lakes and found an average storage loss of 5 per cent from sediment depletion.

Construction costs for new capacity from 1963 to 1981 were $243.40–567.70 per thousand cubic metres (Crowder, 1987). Updating the median from 1981 to 2002 dollars yields $802.60 per thousand cubic metres.

Total costs are calculated using 0.2–5 per cent loss of total national capacity (627.6 billion cubic metres) at the $802.60 per thousand cubic metres replacement value. According to Crowder's analysis, 24 per cent of sediment is from cropland. Reflecting this percentage, final total costs are $241.8–6044.5 million.

(2c) Cost to water conveyance systems

Roadside ditches and irrigation canals become clogged and require sediment removal and maintenance to prevent local flooding. A cost range of $268–790 million is calculated by updating Ribaudo's (1989) figures for these categories and allotting 50 per cent for the contribution of sediment from cropland (Clark et al, 1985).

Subcategories 2d to 2h

These estimates are based primarily on the work of Clark et al (1985) who calculated total erosion effects and applied a multiplier for the percentage due to cropland appropriate to each category. However, erosion from cropland has decreased by 38 per cent since this work (USDA, 2001b). To reflect this improvement, the cropland erosion for each category is multiplied by 62 per cent and updated to 2002 dollars.

(2d) Flood damages

Sediment contributes heavily to floods and flood damages by increasing water volumes and heights and settling on property once floodwaters have abated. Figuring the percentage of flood damages that are due to sediment, as well as the percentage of sediment that is due to agricultural practices, is highly speculative, as indicated by the range of estimates.

The estimate by Clark et al of flood damages due to cropland erosion, but not including loss of life, is revised by the method discussed above to yield a range of $184.5–548.8 million. Ribaudo (1989) reported a cost range of $653–1546 million in 1986 dollars for annual damages due to soil erosion. Using 32 per cent due to cropland, as per Clark et al (1985) and updating to 2002 dollars, the revised range is $343–812 million, but this does not account for decreased erosion rates since the late 1980s.

The Federal Emergency Management Agency (FEMA) reports dollars and lives lost for billion-dollar weather disasters from 1980 to 1997 (FEMA, 2002). Average annual damages are estimated at $6.4 billion in 2002 dollars and 30 lives lost. Numerous studies have arrived at different estimates for the value of a life. An EPA document (1999b) reviews 26 studies and calculates a mean value for avoiding one statistical death to be $5.9 million. The annual cost of floods increases to $6.6 billion when using this valuation for each of the 30 lives lost. Applying percentages of flood damages due to sedimentation (9–22 per cent) and sedimentation due to cropland (32 per cent) as per Clark et al (1985), $190–465 million of this $6.6 billion could be attributable to agriculture.

This last estimate calculated from FEMA data falls within the revised range of Clark et al. High and low range estimates are eliminated as potential outliers. Also, the high end of the valuation based on Ribaudo (1989) may be dropped, considering the revision does not account for the subsequent decrease in cropland erosion. So, the range of $190–548.8 million is used in the national tally.

(2e) Cost to recreational activities

As sediment builds up in lakes and rivers, surface water recreation, including fishing, decreases. Freeman (1982) determined the costs of water pollution that affect recreation. Clark et al used these cost figures and applied a proportion due to sediment as calculated by Vaughan and Russell (1982). Not included were the costs of accidental deaths and injuries caused by increased turbidity. The range revised to 2002 dollars is $540.1–3183.7 million.

(2f) Cost to navigation

Sediment from erosion collects in navigational channels causing groundings and delays, reliance on smaller vessels and lighter loads, and damage to engines due to sand, pollution and algae.

To assess value in this category, Clark et al (1985) included only commercial shipping damages from inland groundings ($20–100 million) and costs for dredging by the US Army Corps of Engineers (USACE), which we update. Accidents and fuel or cargo spills also cause injuries and deaths and damage to public health and the environment; however, these have not been assessed here. According to the Navigation Data Center (USACE, 2003), the FY2002 cost for dredging navigational channels by the Army Corps and its contractors was $922.9 million.

Commercial shipping damages, according to Clark et al, are revised and added to an estimate of national dredging costs. Taking 32 per cent of the result to account for sedimentation from cropland (Clark et al, 1985), the final costs to navigation due to agricultural activities are approximately $304–338.6 million.

(2g) Other in-stream costs: Commercial fisheries and preservation values

Clark et al uses Freeman's (1982) estimates of benefits to commercial fisheries and preservation values that could be gained by controlling water pollution from all sources. Preservation values are non-user values, and, in this case, cleaner water provides non-users with aesthetic and ecological benefits and options for future use. As revised, these annual figures are $224.2–1218.3 million.

Sediment, with its associated contaminants and algal blooms, negatively impacts waterfront property values. A study of lakeside properties in Ohio (Bejranonda et al, 1999) figured benefits to annual rental rates of $23.22–115.90 per ac-ft ($1.88–9.40 per 100 cubic metres) were accrued by reducing the rate of sediment inflow. However, impacts of sediment on property values are not included in the tally because these values cannot be applied nationally and no other sources were found.

(2h) Other off-stream costs: Municipal and industrial users

Municipal and industrial users, including steam power plants, experience increased operational costs associated with dissolved minerals and salts remaining in water received from water treatment suppliers. To avoid scale and algae build-up in water and boiling systems, water needs to be demineralized and treated. Again using revised calculations of Clark et al, these costs are estimated at $197.6–439.7 million.

Category 2 summary

According to this research, total damage to soil resources due to agricultural production is calculated to be $2242.7–13394.7 million per year. Although waterborne erosion is considerable on western rangelands, our sources focused on cropland erosion, which is associated with all of these costs.

Using the above cost totals and 168.8 million hectares of cropland, soil resources are impacted by crop production at a level of $13.29–79.35 per hectare annually. The external cost of the eroded soil itself can be calculated by dividing the total damages due to cropland by 958 million tonnes of erosion from cropland each year. These costs range from $2.34–13.98 per tonne of eroded soil.

The damage totals for impacts on soil resources are among the highest for categories covered in this study. Perhaps, this is because a great deal of research exists on soil erosion from agriculture, which has been a long-term concern. Also, the direct effects of soil erosion may be simpler to track and analyse than damages to other categories.

(3) Damage to air resources

Agriculture damages air resources through:

- particulate matter released by soil erosion;
- volatilization of ammonia (NH_3) from urea and manure fertilizers;
- emissions of nitric oxide (NO) and nitrous oxide (N_2O) from fertilizer applications, field burning and soil denitrification;
- hazardous pollutants from manure storage at concentrated animal feeding operations (CAFOs) (Thorne, 2002);
- emissions of methane (CH_4) from enteric fermentation and eructation (belching) of ruminant livestock and manure storage (Cavigelli et al, 1998; USEPA, 2003).

Some of these releases are greenhouse gases, which interact with the environment and affect human and ecological health. They cause climate change through atmospheric warming, aggravate pulmonary and respiratory functioning, degrade building materials and contribute to the acidification and eutrophication of water resources.

Greenhouse gas emissions from agricultural sources in 2001 totalled 474.9 million tonnes carbon dioxide equivalents, which represents approximately 7 per cent of total greenhouse gas emissions in the US, including 70 per cent of all nitrous oxide emissions from anthropogenic activities and 25 per cent of total CH_4 emissions (USEPA, 2003). The net impact of agriculture is lessened by the up take of carbon by agricultural soils, and policy efforts are underway to promote practices that will increase this carbon sequestration. Agricultural soils provided a sink for 15.2 million tonnes carbon dioxide equivalents in 2001 (USEPA, 2003).

Two sources of valuation for greenhouse gases provide a range of estimates. A study by Titus (1992) considers impacts of climate change to the US, including effects on agricultural production, increases in energy consumption, sea level rise, heat-related deaths and change in forest biomass. The study calculates that a doubling of CO_2 (and equivalents) could cost \$37–351 billion per year (1992 dollars). Also, the marginal cost of climate change from burning one gallon of gasoline is calculated at \$0.16–0.36, at a 3 per cent discount rate. This translates to \$20–50 per tonne carbon dioxide equivalents (2002 dollars).

The Chicago Climate Exchange enables member corporations, municipalities and other institutions to trade greenhouse gas credits in an effort to 'determine the most cost-effective means of reducing overall emissions' (Chicago Climate Exchange, 2004). Members who have reduced emissions receive credits, which can be sold to other members. The final market price for 2003 carbon dioxide equivalents closed at \$0.98 per tonne. This is much lower than the range calculated in the Titus study. This is not surprising because the trading price is what companies are willing to pay for emission reductions and does not necessarily reflect health and environmental externalities. Also, participation in the Exchange is strictly voluntary.

However, in the interest of being conservative, we use \$0.98 per tonne carbon dioxide equivalents. As discussed, net emissions from agriculture in 2001 were 459.7 million tonnes carbon dioxide equivalents, according to the US Emissions Inventory (USEPA, 2003). Total damage from agriculture is then calculated at \$450.5 million.

EPA emission data suggest that 63 per cent of this cost is from crop production (\$283.8 million) and 37 per cent is from livestock sources (\$166.7 million), as follows:

- Crop – soil management, burning crop residues and rice cultivation;
- Livestock – enteric fermentation and manure management.

Using the above cost totals and 168.8 million hectares of cropland, air resources are impacted by cropland at a level of \$1.68 per hectare annually.

(4) Damage to wildlife and ecosystem biodiversity

These costs involve impacts to bird, fish and insect populations, which, in turn, influence ecosystem biodiversity. With approximately 447 million kilograms of active ingredients used in agricultural production (Gianessi and Marcelli, 2000), pesticides affect ecosystem balance.

Our primary valuation source is a study on the environmental impacts of pesticides by Pimentel et al (1992). We acknowledge that since this research was done formulations and application methods of some pesticides have changed to reduce toxicity. For example, the use of granular carbofuran has been severely restricted since 1994 (Pesticide Management Education Program, 1991). The EPA estimated in the 1980s that granular carbofuran killed one to two million birds each year. In spite of this, the restrictions continue to be challenged as evidenced by the recent emergency use request of rice growers in Louisiana. The EPA initially approved use of granular carbofuran on 4050 hectares, but this was reduced to 1010 hectares after public comments were received (American Bird Conservancy, 2002; National Coalition Against the Misuse of Pesticides, 2002).

Aside from the effects of pesticide use, we do include one calculation to value fish killed by manure spills. But, other known environmental stressors associated with agriculture are not represented here. These include inorganic fertilizer runoff and its impact on aquatic ecosystems and the suppression of biodiversity by monocultural practices. Again, impacts on natural ecosystems are difficult to track and analyse and valuation studies are few. Our coverage of this category is far from comprehensive.

(4a) Honeybee and pollination losses

Pollinators, especially honeybees, are fundamental to ecosystem and agricultural stability. Various studies have attempted to value the agricultural services of pollinators. Southwick and Southwick (1992) estimated \$1.6–5.7 billion in total annual benefit to agricultural consumers in the US from honeybee pollination. Morse and Calderone (2000) claim the annual value of honeybee pollination to be \$14.6 billion, in terms of increased yields and product quality.

For our purposes, the more conservative economic impact of pesticide use on honeybees as calculated by Pimentel et al (1992) is used. Their estimate of \$319.6 million is figured in terms of colony losses, reduced honey production and crop pollination and the cost of bee rentals. Assuming original reporting in 1992 dollars, the annual figure is \$409.8 million in 2002 dollars.

(4b) Loss of beneficial predators

Most pesticide applications not only affect the primary crop pest, but also natural enemies of the pest. As the population of beneficial insects drops, outbreaks of secondary pests occur, which in turn lead farmers to apply more pesticide. The cost of these additional applications and crop losses associated with secondary pests is \$666.8 million, updating the figure as per Pimentel et al (1992).

Although these costs could be considered on-site, they are included because the invertebrate loss due to broad-spectrum pesticides affects not only crop production, but also the ecosystem as a whole. In addition, pesticides may harm microorganisms. The number and activity of microorganisms in the soil are measures of soil and ecosystem health, as they break down organic matter and cycle nutrients.

(4c) Fish kills due to pesticides

Pesticides contaminate aquatic environments, poisoning fish and damaging their food sources and habitat. It is difficult to calculate losses in severe fish kill events and low-level poisonings are often not detected. Pimentel et al (1992) use EPA data to estimate 6–14 million fish deaths per year due to pesticides and values of freshwater fish from the American Fisheries Society (1982), reflecting commercial hatchery production costs of various fish species. We calculate the average of these values, omitting sturgeon and paddlefish over 38 centimetres long, at $1.67 per fish in 1980 dollars, or $3.65 in 2002 dollars. These numbers yield a damage range of $21.9–51.1 million.

(4d) Fish kills due to manure spills

Manure spills, leaks and dumping by animal feeding operations into surface waters also cause damage to aquatic environments and can be partially valued by the number of fish killed in documented events. A report by the Clean Water Network (2000) records information on feedlot spills and associated fish kills in ten states from 1995 to 1998. Most of the data were collected from state agency databases and reports. More than 13 million fish were killed in over 200 documented manure pollution events. This does not reflect the effects of smaller spills and cumulative impacts and, of course, is not a national count. However, because a high number of animal feeding operations are located in the states included in this report, these numbers are used as a rough proxy for a national estimate. Thirteen million is divided by four years and multiplied by the value of $3.65 per fish given earlier. The estimated annual cost is conservatively set at $11.9 million.

(4e) Bird kills due to pesticides

Birds exposed to pesticides may be poisoned directly or may ingest pesticide residues with prey and seeds. Pesticides affect the life cycle and reproductive ability of birds and their habitats. Toxicity is difficult to quantify, however, considering avian risk assessments customarily test only one to three bird species; the total number of bird species globally is estimated at 10,000, and over 800 species occur in the US and Canada (Mineau et al, 2001).

Pimentel et al (1992) figure approximately 672 million birds are directly exposed to pesticides on cropland and that 10 per cent of these birds die. The study provides values for a bird's life ranging from $0.40 to $216 to $800. These figures reflect, respectively, cost per bird for bird watching, hunting costs per bird felled and the cost of rearing and releasing a bird to the wild. The higher figures may be considered inappropriate because they are associated with species not as directly affected by agricultural pesticides. By updating the lowest, most conservative valuation to $0.51 per bird death, the cost of bird kills due to pesticides is $34.5 million. This total does not address life cycle and reproductive damages due to poisonings.

Category 4 summary

Total annual damage to wildlife and ecosystem biodiversity due to agricultural production, according to this research, is calculated to be $1144.9–1174.1 million. Pesticide use for crop production is associated with all of the costs, except for fish kills due to manure spills from livestock operations. These external costs can be split as follows: $1133–1162.2 million in damages due to crop production and $11.9 million due to livestock production. Considering the impacts in terms of pesticide use, each kilogram of active ingredient, of 447 million kilograms applied, generates approximately $2.55 in external costs.

Using the above cost totals and 168.8 million hectares of cropland, crop production's injuries to biodiversity cost $6.71–6.89 per hectare annually.

The external costs calculated here are substantial and suggest the need for a comprehensive examination of pesticide products and application methods. To curb manure spills, regulations for manure handling at animal feeding operations should continue to be reviewed and enforced and the promotion of other options for livestock finishing should be considered.

(5) Damage to human health: Pathogens

According to the Centers for Disease Control and Prevention (CDC), more than 250 food-transmitted diseases cause an estimated 76 million illnesses, 325,000 hospitalizations and 5200 deaths annually in the US (CDC, 2002). A Council for Agricultural Science and Technology (CAST) task force estimated microbial foodborne disease cases to number 6.5–33 million annually, with deaths possibly as high as 9000 (CAST, 1994).

Estimates for this category include costs of illnesses associated with foodborne pathogens and costs to the food industry to comply with pathogen reduction regulations. Data are not readily available for other societal costs, such as those incurred by the public health sector or from antibiotic resistance in humans. A recent CAFO air quality study in Iowa describes antibiotic resistance as 'a health threat of great concern' (Iowa State University and The University of Iowa Study Group, 2002, pp1–11).

Costs of illnesses associated with waterborne pathogens are not included because states should have implemented the Interim Enhanced Surface Water Treatment Rule (IESWTR) by 1 January 2002. The avoidance benefit of the IESWTR for *Giardia* spp. and *Cryptosporidium parvum* infections due to agriculture is estimated to be between $628 million and $1 billion annually (USEPA, 1997c, 1998a).

(5a) Cost of foodborne illnesses

Most microbial contamination stems from the processing and packaging of animal products. According to a USDA web page (2000a), 'Simple changes in food processing and handling practices can eliminate at least 90 per cent of foodborne illnesses.' This suggests that 10 per cent of foodborne pathogen contamination arises from production and meal preparation. Zero contamination is not realistic and other entry points for contamination may not be identified, so we estimate that 3 per cent of the health costs in this category are attributable to agricultural production unless otherwise noted.

Pathogens causing illness may be bacterial, parasitic, fungal or viral. Cost studies by the USDA's Economic Research Service (ERS) have focused on common bacterial agents found in meat, eggs and dairy products. Other food sources include some vegetables, fruits, juices and seafood.

The ERS estimates the annual costs for five bacterial pathogens at $6.9 billion in 2000 dollars (USDA, 2001c). These pathogens are *Campylobacter* spp., *Salmonella*, *E. coli* O157:H7, *E. coli* non-O157 STEC and *Listeria monocytogenes*. In addition to these, Buzby et al (1997) provide damage estimates for the bacteria *Clostridium perfringens* and *Staphylococcus aureus* and the parasite *Toxoplasma gondii* totalling $4.5 billion (1995 dollars). Updating these figures and attributing 3 per cent of the totals to agricultural production, the estimate for the costs of illnesses and deaths from these common pathogens is $375.7 million annually.

This is conservative given that unidentified agents cause the majority of illnesses, and estimates have been calculated only for the common, known pathogens. The CDC (Mead et al, 1999) estimates that 82 per cent of foodborne illnesses and 65 per cent of deaths are caused by unknown pathogens. Also, many illnesses go unreported or are not diagnosed as food-related.

Furthermore, these costs include only the impacts on households, in terms of lost productivity and income, medical costs and premature death. Household costs not valued include pain and disability, travel costs for medical care, loss of work time for caregivers and chronic health complications.

(5b) Cost to industry to comply with HACCP rule

In 1997, USDA's Food Safety and Inspection Service (FSIS) issued the first stage of the Pathogen Reduction/Hazard Analysis and Critical Control Point (HACCP) systems rule to meet targets for microbial pathogen reduction. FSIS cites industry costs for meat and poultry plants to comply with HACCP regulations that range from $1.3–2.1 billion in year 2000 dollars (USDA, 2001a). These estimates are based on four scenarios of different pathogen control percentages and interest rates. The estimate for costs due to agricultural production is $40.7–65.8 million, which is 3 per cent of the range of industry costs and updated to 2002 dollars. Costs of complying with HACCP may be considered health costs internalized by the food processing industry, but this 3 per cent is viewed as a cost caused by agricultural production practices, which is externalized beyond the farm gate to processors and consumers.

Category 5 summary

According to this research, damage to human health from foodborne pathogens due to livestock production is calculated at $416.4–441.5 million per year. Although contamination often originates during processing and preparation, livestock health and production methods contribute to a large number of illnesses and should be evaluated to fully address food safety issues. Growing evidence that antibiotic use in livestock increases the resistance of foodborne pathogens reinforces the need to further explore the role of production in this health threat (Iowa State University and The University of Iowa Study Group, 2002).

(6) Damage to human health: Pesticides

Pesticides endanger human health through direct exposure, release into the environment and residues on food. Exposure to pesticides, depending on toxicity and quantity, can cause poisoning, eye damage, respiratory ailments, disruption of the endocrine system (USEPA, 2002c), birth defects, nerve damage, cancer and other effects that may develop over time (USEPA, 2001c). Of particular concern are pesticides that act as endocrine disruptors:

> The endocrine system consists of a set of glands and the hormones they produce that help guide the development, growth, reproduction, and behavior of animals including human beings... EPA is concerned about the growing body of evidence that some man-made chemicals may be interfering with normal endocrine system functioning in humans and other animals. (USEPA, 1997d)

Detectable levels of pesticides have been found on approximately 35 per cent of purchased food in the US (Pimentel et al, 1992). Farm workers who handle and apply pesticides face distinct risks. More than 58,000 unintentional poisonings by agricultural pesticides were reported to the American Association of Poison Control Centers in 2002 (Watson et al, 2003).

(6a) Pesticide poisonings

Very little research has been done to identify and quantify health impacts of pesticides on a national scale for the US. Studies in the Philippines and Ecuador document health effects and calculate reduction in farmer productivity caused by pesticide use (Antle et al, 1998; Antle and Pingali, 1994; Cole et al, 2000; Crissman et al, 1994; Rola and Pingali, 1993). These results, however, are not transferable to agriculture in the US, considering differences in farmer training and production methods. Here, we rely on Pimentel et al (1992), who calculate the costs of pesticide poisonings and deaths based on hospitalizations, outpatient treatment, loss of work and fatalities due to accidental poisonings and treatment costs for pesticide-induced cancers. Their estimate of $787 million ($1009 million in 2002 dollars) is based, in part, on speculation regarding the incidence of illness and death. However, it could be regarded as conservative considering the number of poisonings reported to control centres. Also, the estimate does not include unreported or misdiagnosed illnesses or costs of chronic ailments, other than cancer, associated with pesticide exposure. In addition, detection techniques are not available for the majority of pesticides used in the US and their health effects have not been determined (Pimentel et al, 1992).

Part of this valuation may be considered double-counting with the water treatment costs in Subsection 1c. However, water treatment processes do not prevent all waterborne exposure and associated illnesses.

Category 6 summary

The cost to human health from pesticides used in crop production is $1009 million annually. Using this valuation and 168.8 million hectares of cropland, human health is affected by pesticide applications on cropland at a level of $5.98 per hectare annually. In terms of pesticide use, the impact to human health translates to $2.26 per kilogram active ingredient. This is a substantial external cost. The damages reported here and in Subsections 1 and 4 call for increased scrutiny of the human and environmental effects of chemical use in agricultural production.

In 2002, farmers spent $8.2 billion on pesticides in the US (USDA, 2004). But, this retail cost reflects less than 80 per cent of the actual cost of pesticide use, when considering the $2253.9–2283.1 million in damages to water resources, wildlife and ecosystem biodiversity and human health calculated here.

Summary

Agricultural production in the US negatively impacts water, soil, air, wildlife and human health at an estimated cost of $5.7–16.9 billion (£3.3–9.7 billion) per year. This is the aggregate cost range from the studies reviewed. The breakdown of these costs by production type, as indicated in Table 3.1, is $4969.3–16,150.5 million per year of impacts due to crop production and $713.6–738.7 million due to livestock production. With the estimate of 168.8 million hectares of cropland in the US, total external cost per cropland hectare is calculated at $29.44–95.68 (£16.87–54.82), as shown in Table 3.3 by damage category.

These figures offer a broad, preliminary view of how the externalities of agriculture encumber society. And yet, these numbers are conservative, considering we are limited by the complexities of assigning monetary values to environmental and health impacts and the lack of related data.

Table 3.3 *Annual external costs of crop production per hectare*

Damage category	*Cost*
Water resources	$1.78
Soil resources	$13.29–79.35
Air resources	$1.68
Biodiversity	$6.71–6.89
Human health – pesticides	$5.98
Totals	$29.44–95.68 (£16.87–54.82)

Comparing our findings with a more comprehensive list of agricultural externalities illustrates the incomplete nature of our national tally. For this we turn to social and natural resource accounting efforts, which attempt to incorporate human and environmental capital assets and flows into traditional income and product measures. These assets are not priced in the current market economy and require valuation to be included in social accounts. We refer the reader to other sources for further information on systems of accounts:

- *System of National Accounts* (Commission of the European Communities et al, 1993);
- *Handbook of National Accounting: Integrated Environmental and Economic Accounting* (United Nations et al, 2003);
- *A System of Economic Accounts for Food and Agriculture* (Food and Agriculture Organization, 1996);
- *Environmental Indicators for Agriculture* (Organisation for Economic Co-operation and Development, 2001).

The environmental indicators listed in Table 3.4 are a combination of those provided in *Environmental Indicators for Agriculture* and Cabe and Johnson (1990), as well as others we have suggested. Please refer to these sources for further explanation of indicators. Also shown in Table 3.4 are the categories for which we have identified national valuation data.

Table 3.4 *Agri-environmental indicators*

Indicator	*National valuation data for the US*
Nutrient use: balance, efficiency, human health risks	Water treatment for nitrates
Pesticide use and risks	Water treatment Hospitalizations, outpatient treatment, loss of work, fatalities due to accidental poisonings and treatment costs for pesticide-induced cancers
Water use: intensity, efficiency, stress	
Human health risks of production: antibiotic use, waterborne and foodborne pathogens	Water treatment for microbial pathogens Some household costs for illnesses caused by common foodborne pathogens Cost to industry to comply with HACCP rule
Soil erosion by water	For cropland erosion only:
Commercial fisheries	X
Flood damage	X
Industrial users	X
Preservation values	X
Recreation	X

Table 3.4 *(continued)*

Indicator	*National valuation data for the US*
Salinity	
Transportation/navigation	X
Water conveyance	X
Water storage	X
Water treatment	X
Soil erosion by wind	
Human health	
Soiling	
Visibility	
Ground and surface water quality: risks and state	Water treatment for pathogens, nitrates, pesticides
Land conservation	
Water retaining capacity	
Off-farm sediment flow/soil retaining capacity	
Greenhouse gas emissions	X
Biodiversity	
Genetic diversity	
Species diversity: wild, non-native	Impacts to honeybees, beneficial predators, fish, birds
Ecosystem diversity	
Wildlife habitats	
Intensively farmed agricultural habitats	
Semi-natural agricultural habitats	
Uncultivated natural habitats	
Habitat matrix	
Aquatic habitats	
Landscapes	
Structure	
Environmental features, land-use patterns	
Man-made objects/cultural features	
Management	
Costs and benefits	

Clearly, further research is needed on external costs of agriculture, including detailed studies in each impact category, by geographical region and by production type. Comparative valuation studies also would be instructive, i.e. examinations of grazing *vs* feedlot production of livestock or monocropping *vs* diverse cropping systems. In comparing production methods, trade-offs should be taken into account. For instance, lower pesticide use often requires increased tillage and possibly causes more soil erosion. Also of interest would be an examination of positive, or beneficial, externalities provided by agriculture, i.e. carbon sequestration, wildlife habitat and aesthetics. Pricing these services may open the door to policy decisions that compensate producers for such 'products'.

Conclusion

Many in the US pride themselves on our 'cheap' food. But, this study demonstrates that consumers pay for food well beyond the grocery store checkout. We pay for food in our utility bills and taxes and in our declining environmental and personal health. These costs total, conservatively, \$5.7–16.9 billion (£3.3–9.7 billion) each year. We also support at least \$3.7 billion (£2.1 billion) annually in efforts to regulate the present system and mitigate damages. Additional public costs of agricultural production in the US include direct subsidies and other support mechanisms for farmers. These are not included in our final tally but must be considered in the true cost of food.

What can be done? By using 'ecological' or 'sustainable' methods, some agricultural producers claim to be internalizing many of these external costs. However, the market and policy structure in which most producers operate offers narrow return margins and discourages changes in production methods. Considering this, the partial estimate of damage costs presented here promotes responsible, creative policy actions to acknowledge and internalize the externalities of production practices that are generally accepted and widespread.

Furthermore, the estimates presented in this chapter are conservative for reasons beyond the need for more valuation data. Many industrial agricultural practices present us with environmental risks that have unknown potential consequences. Potentialities are difficult to define because effects are diffuse in time and location. Some of these risks have been acknowledged scientifically but not necessarily politically, i.e. ecosystem behaviour in a mono-cropped environment, antibiotic resistance in humans, loss of pollinators.

Political intention is required to reassess and reform agricultural policy. Programmes that highlight sustainable methods rather than destructive, risky practices would be a start in internalizing the true costs of the present system.

From Pesticides to People: Improving Ecosystem Health in the Northern Andes

Stephen Sherwood, Donald Cole, Charles Crissman and Myriam Paredes

Introduction

Since the early 1990s, a number of national and international organizations have been working with communities in Carchi, Ecuador's northernmost province, on projects to assess the role and effects of pesticide use in potato production and to reduce its adverse impacts. These are INIAP (National Institute of Agricultural Research from Ecuador), CIP (International Potato Center), Montana State University (US), McMaster University and University of Toronto (Canada), Wageningen University (The Netherlands), and the FAO's (Food and Agriculture Organization) Global Integrated Pest Management (IPM) Facility.

These projects have provided quantitative assessments of community-wide pesticide use and its adverse effects. Through system modelling and implementation of different alternatives, we have demonstrated the effectiveness of different methods to lessen pesticide dependency and thereby improve ecosystem health. Meanwhile, the principal approach to risk reduction of the national pesticide industry continues to be farmer education through 'Safe Use' campaigns, despite the safe use of highly toxic chemicals under the social and environmental conditions of developing countries being an unreachable ideal. These conflicting perspectives and the continued systematic poisoning of many rural people in Carchi have motivated a call for international action (Sherwood et al, 2002).

The project members have worked with interested stakeholders to inform the policy debate on pesticide use at both the provincial and national levels. Our position has evolved to include the reduction of pesticide exposure risk through a combination of hazard removal (in particular, the elimination of highly toxic pesticides from the market), the development of alternative practices and ecological

education. The experience reported here has led us to conclude that more knowledge-based and socially oriented interventions are needed. These must be aimed at political changes for enabling new farmer learning and organizational capacity, differentiated markets and increased participation of the most affected parties in policy formulation and implementation. Such measures involve issues of power that must be squarely faced in order to foster continued transformation of potato production in the Andes towards sustainability.

Potato Farming in Carchi

The highland region of Carchi is part of a very productive agricultural region, the Andean highlands throughout Northern Ecuador, Colombia and Venezuela. Situated near the equator, the region receives adequate sunlight throughout the year which, coupled with evenly distributed rainfall, means that farmers can continuously cultivate their land. As a result, the province is one of Ecuador's most important producers of staple foods, with farmers producing nearly 40 per cent of the national potato crop on only 25 per cent of the area dedicated to potato (Herrera, 1999).

Carchi is a good example of the spread of industrialized agricultural technologies in the Americas during the Green Revolution that began in the 1960s. A combination of traditional sharecropping, land reform, market access and high-value crops provided the basis for rural economic development (Barsky, 1984). Furthermore, as a result of new revenues from the oil boom of the 1970s, the Ecuadorian government improved transportation and communication infrastructure in Carchi, and the emerging agricultural products industry was quick to capitalize on the availability of new markets. A typical small farm in Carchi is owned by an individual farm household and consists of several separate, scattered plots with an average area of about six hectares (Barrera et al, 1998).

Not surprisingly, agricultural modernization underwent a local transformation. In Carchi, mechanized, agrochemical and market-oriented production technologies are mixed with traditional practices, such as sharecropping arrangements, payments in kind, or planting in *wachu rozado* (a pre-Colombian limited tillage system) (Paredes, 2001). Over the last half-century, farming in Carchi has evolved towards a market-oriented potato-pasture system dependent on external inputs. Between 1954 and 1974 potato production increased by about 40 per cent and worker productivity by 33 per cent (Barsky, 1984). Until recently, the potato growing area in the province continued to increase, and yields have grown from about 12t/ha in 1974 to about 21t/ha today, a remarkable three times the national average (Crissman et al, 1998a).

To confront high price variability in potato (by factors of 5–20 in recent years), farmers have applied a strategy of playing the 'lottery', which involves continual production while gambling for high prices at harvest to recover overall investment. Nevertheless, the dollarization of the Ecuadorian Sucre in 2000 led to triple digit inflation and over 200 per cent increase in agricultural labour and input costs over three years (World Development Index, 2003). Meanwhile, open trade with neighbouring Colombia and Peru has permitted the import of cheaper commodities. As a result of a trend towards increased input costs and lower potato prices, in 2003 Carchense farmers responded by decreasing the area planted in potato from about 15,000ha in previous years to less than 7000ha. It remains to be seen how farmers ultimately will compensate for the loss of competitiveness brought about by dollarization.

Carchi farmers of today rely on insecticides to control the tuber-boring larva of the Andean weevil (*Premnotrypes vorax*) and a variety of foliage damaging insects. They also rely on fungicides to control late blight (*Phytophtera infestans*). One economic study of pesticides in potato production in Carchi confirmed that farmers used the products efficiently (Crissman et al, 1994), and later attempts during the 1990s by an environmental non-governmental organization (NGO) to produce pesticide-free potatoes in Carchi failed (Frolich et al, 2000). After 40 years inorganic fertilizers and pesticides appear to have become an essential part of the social and environmental fabric of the region (Paredes, 2001).

Pesticide Use and Returns

Our 1990s study of pesticide use found that farmers applied 38 different commercial fungicide formulations (Crissman et al, 1998a). Among the fungicides used, there were 24 active ingredients. The class of dithiocarbamate contact-type fungicides were the most popular among Carchi farmers, with mancozeb contributing more than 80 per cent by weight of all fungicide active ingredients used. The dithiocarbamate family of fungicides has recently been under scrutiny in the Northern Andes due to suspected reproductive (Restrepo et al, 1990b) and mutagenic effects in human cells (Paz-y-Mino et al, 2002). Similar concerns have been raised in Europe and the US (USEPA, 1992; Lander et al, 2000).

Farmers use three of the four main groups of insecticides in 28 different commercial products. Although organochlorine insecticides can be found in Ecuador, farmers in Carchi did not use them. The carbamate group was represented only by carbofuran, but this was the single most heavily used insecticide – exclusively for control of the Andean weevil. Carbofuran was used in its liquid formulation, even though it is restricted in North America and Europe due to the ease of absorption of the liquid and the high acute toxicity of its active ingredient. Another 18 different active ingredients from the organophosphate and pyrethroid groups were employed to control foliage pests, though only four were used on more than 10 per cent of plots. Here the OP methamidophos, also restricted in North America due to its high acute toxicity, was the clear favourite. Carbofuran and methamidophos, both classified as highly toxic (1b) insecticides by the WHO, respectively made up 47 per cent and 43 per cent of all insecticides used (by weight of active ingredient applied). In sum, 90 per cent of the insecticides applied in Carchi were highly toxic. A later survey by Barrera et al (1998) found no significant shifts in the products used by farmers.

Most insecticides and fungicides come as liquids or wettable powders and are applied by mixing with water and using a backpack sprayer. Given the costs associated with spraying, farmers usually combine several products together in mixtures known locally as cocktails, applying all on a single pass through the field. On average, each parcel receives more than seven applications with 2.5 insecticides and/or fungicides in each application (Crissman et al, 1998a). Some farmers reported as many as seven products in a single concoction. On many occasions different commercial products were mixed containing the same active ingredient or different active ingredients intended for the same type of control. Women and very young children typically did not apply pesticides: among the 2250 applications that we documented, women made only four.

Product and application costs together account for about one-third of all production costs among the small and medium producers in the region. The benefit to yields (and revenues) from using pesticides exceeded the additional costs of using them (including only direct production costs such as inputs and labour but not the costs of externalities). Nevertheless, Crissman et al (1998a) found that farmers lost money in four of ten harvests, largely due to potato price fluctuations and price increases in industrial technologies, particularly mechanized land preparation, fertilizers and pesticides, that combined can represent 60 per cent of overall production outlays. Unforeseen ecological consequences on natural pest control mechanisms, in particular parasitoids and predators in the case of insect pests and selective pressure on *Phytophtora infestans* in the case of disease, raises further questions about the real returns on pesticides (Frolich et al, 2000). As we shall see, long-term profitability of pesticide use is even more questionable when associated human health costs to applicators and their families are taken into account.

Pesticide Exposure and Health Effects

Based on survey, observational and interview data, the majority of pesticides are bought by commercial names. Only a small minority of farmers reported receiving information on pesticide hazards and safe practices from vendors (Espinosa et al, 2003). Pesticide storage is usually relatively brief (days to weeks) but occurs close to farmhouses because of fear of robbery. Farmers usually mix pesticides in large barrels without gloves, resulting in considerable dermal exposure (Merino and Cole, 2003). Farmers and, on larger farms, day labourers apply pesticides using backpack sprayers on hilly terrain. Few use personal protective equipment (PPE) for a variety of reasons, including social pressure (e.g. masculinity has become tied to the ability to withstand pesticide intoxications), and the limited availability and high cost of equipment. As a result, pesticide exposure is high. During pesticide applications, most farmers wet their skin, in particular the back (73 per cent of respondents) and hands (87 per cent) (Espinosa et al, 2003). Field exposure trials using patch-monitoring techniques showed that considerable dermal deposition occurred on legs during foliage applications on mature crops (Cole et al, 1998b). Other studies have shown that additional field exposure occurs in the field during snack and meal breaks, when hand washing rarely occurs (Paredes, 2001).

Family members are also exposed to pesticides in their households and in their work through a multitude of contamination pathways. Excess mixed product may be applied to other tuber crops, thrown away with containers in the field, or applied around the house. Clothing worn during application is often stored and used repeatedly before washing. Contaminated clothing is usually washed in the same area as family clothing, though in a separate wash. Extent of personal wash up varies but is usually insufficient to remove all active ingredients from both the hands of the applicator and the equipment. Separate locked storage facilities for application equipment and clothing are also uncommon. Swab methods have found pesticide residues on a variety of household surfaces and farm family clothing (Merino and Cole, 2003).

Pesticide poisonings in Carchi are among the highest recorded in developing countries (Cole et al, 2000). In active poisoning surveillance, though there were some suicides and accidental exposures, most reported poisonings were of applicators. While the extensive use of fungicides causes dermatitis, conjunctivitis and associated skin problems (Cole et al, 1997a), we focused our attention on neurobehavioural disorders caused by highly toxic methamidophos and carbofuran. The results were startling.

The health team applied a WHO recommended battery of tests to determine the effects on peripheral and central nervous system functions (Cole et al, 1998a, 1997b). The results showed high proportions of the at-risk population affected, both farmers and their family members. Average scores for farm members were a standard deviation below the control sample, the non-pesticide population from the town. Over 60 per cent of rural people were affected and women, although not commonly active in field agriculture, were nearly as affected as field workers. Alarmingly, both Mera-Orcés (2001) and Paredes (2001) found that poisonings and deaths among young children were common in rural communities.

Contamination resulted in considerable health impacts that ranged from subclinical neurotoxicity (Cole et al, 1997a, 1998a), poisonings with and without treatment (Crissman et al, 1994) to hospitalizations and deaths (Cole et al, 2000). In summary, human health effects included poisonings (at a rate of 171/100,000 rural population), dermatitis (48 per cent of applicators), pigmentation disorders (25 per cent of applicators), and neurotoxicity (peripheral nerve damage, abnormal deep tendon reflexes and coordination difficulties). Mortality due to pesticide poisoning is among the highest reported anywhere in the world (21/100,000 rural population). These health impacts were predominantly in peri-urban and rural settings. This high incidence of poisoning may not be because the situation is particularly bad in Carchi, but because researchers sought systematically to record and document it.

Acute pesticide poisonings led to significant financial burdens on individual families and the public health system (Cole et al, 2000). At the then current exchange rates, median costs associated with pesticide poisonings were estimated as follows: public health care direct costs of \$9.85/case; private health costs of \$8.33/case; and lost time indirect costs for about six worker days of \$8.33/agricultural worker. All of these were over five times the daily agricultural wage of about \$1.50 at the time (1992). Antle et al (1998a) showed that the use of some products adversely affects farmer decision making capacity to a level that would justify worker disability payments in other countries. Neither group of researchers included financial valuation of the deaths associated with pesticide poisonings nor the effects of pesticides on quality of life, both of which would substantially increase the overall economic burden of illness estimates.

A Myth – the Highly Toxics can be Safely Used

Following the research results, limitations in the pesticide industry's safe use of pesticides (SUP) campaign became apparent. In a letter to the research team, the Ecuadorian Association for the Protection of Crops and Animal Health (APCSA, now called Crop Life Ecuador) noted that an important assumption of SUP was that exposure occurred because of 'a lack of awareness concerning the safe use and handling of [pesticide] products'. Although our Carchi survey showed a low percentage of women in farm families had received any training on pesticides (14 per cent), most male farmers (86 per cent) had received some training on pesticide safety practices. Furthermore, labels are supposed to be an important part of the 'hazard communication process' of salesmen. Yet our work in Carchi indicated that farm members often could not decipher the complex warnings and instructions provided on most pesticide labels.

Although 87 per cent of the population in our project area was functionally literate, over 90 per cent could not explain the meaning of the coloured bands on pesticide containers indicating pesticide toxicity. Most believed that toxicity was best ascertained through the odour of products, potentially important for organophosphates with sulphur groups but not generalizable to all products that are impregnated by formulators for marketing purposes. Hence even the universal, seemingly simple toxicity warning system of coloured bands on labels has not entered the local knowledge system. If industry is seriously concerned about informing farmers of the toxicity of its products, it should better match warning approaches to current perceptions of risk, such as considering using toxicity-related odour indicators.

In addition, the SUP campaign's focus on pesticides and PPE is misguided. Farmers regard PPE as uncomfortable and 'suffocating' in humid warm weather, leading to the classic problem of compliance associated with individually oriented exposure reduction approaches (Murray and Taylor, 2000). Examination of the components of the classic industrial hygiene hierarchy of controls (Table 4.1) shows PPE to be among the least effective controls and suggests that the industry

Table 4.1 *Hierarchy of controls for reducing pesticide exposure*

Most effective	
1	Eliminate more highly toxic products, e.g. carbofuran and methamidophos
2	Substitute less toxic, equally effective alternatives
3	Reduce use through improved equipment, e.g. low volume spray nozzles
4	Isolate people from the hazard, e.g. locked separate pesticide storage
5	Label products and train applicators in safe handling
6	Promote use of personal protection equipment
7	Institute administrative controls, e.g. rotating applicators
Least effective	

Source: Adapted from Plog et al, 1996

strategy of prioritizing PPE is similar to locking the stable after the horse has bolted. Our research has shown the ineffectiveness of product labelling (point 5). Isolation (point 4) is difficult in open environments such as field agriculture where farming infrastructure and housing are closely connected and some contamination of the household is virtually inevitable, particularly in poorer households. Priority should be given to other more effective strategies of exposure reduction, beginning with point 1: eliminating the most toxic products from the work and living environments. Likewise, this is the highest priority of the Integrated Production and Pest Management (IPPM) 2015 initiative.

INIAP, the Ecuadorian agricultural research institute, is prepared to declare that alternative technologies exist for the Andean weevil and foliage pests and that highly toxic pesticides are not necessary for potato production and other highland crops in Ecuador (Gustavo Vera, INIAP Director General of Research, personal communication). Meanwhile, pesticide industry representatives have privately acknowledged that they understand that highly toxic pesticides eventually will need to be removed from the market. Nevertheless, the Ecuadorian Plant and Animal Health Service (SESA) and Crop Life Ecuador have taken the position that they will continue to support the distribution and sale of WHO Class I products in Ecuador until the products are no longer profitable or that it is no longer politically viable to do so.

One seven-year study by Novartis (now Syngenta) found that SUP interventions in Latin America, Africa and Asia were expensive and largely ineffective, particularly with smallholders (Atkin and Leisinger, 2000). The authors argue that 'the economics of using pesticides appeared to be more important to [small farmers] than the possible health risks' (p121). The most highly toxic products are the cheapest on the market in Carchi, largely because the patents on these early generation products have expired, permitting free access to chemical formulas and competition, and because farmers have come to accept the personal costs associated with poisonings.

Policies and Trade-offs

Pesticide use in agricultural production conveys the benefit of reducing losses due to pests and disease. That same use, however, can cause adverse environmental and health impacts. Previously, we cited a study that showed that pesticide use by farmers was efficient from a narrow farm production perspective. Nevertheless, that study examined pesticide use solely from the perspective of reducing crop losses. If the adverse health and environmental effects were also included in the analysis, the results would be different. Integrated assessment is one method for solving this analytical problem. The Carchi research team devised an innovative approach to integrated assessment called the Trade-off Analysis (TOA) method (Antle et al, 1998b; Stoorvogel et al, 2004).

The TOA method is an interactive process to define, analyse and interpret results relevant to policy analysis. At its heart is a set of linked economic, biophysical and health models inside a user shell called the TOA Model. Based on actual dynamic data sets from the field, we used simulations in the TOA method to examine policy options for reducing pesticide exposure in Carchi.

The policy options we explored were a combination of taxes or subsidies on pesticides, price increases or declines in potatoes, technology changes with IPM, and the use of personal protective equipment. We examined the results in terms of farm income, leaching of pesticides to groundwater and health risks from pesticide exposure. Normally, policy and technology changes produce trade-offs – as one factor improves, the other factor worsens. Our analysis of pesticide taxes and potato price changes produced such a result. As taxes decrease and potato prices increase, farmers plant more of their farm with potatoes and tend to use more pesticide per hectare. Thus a scenario of pesticide subsidies and potato price increases produce growth in income and increases in groundwater contamination and health risks from pesticide exposure.

With the addition of technology change to these price changes, the integrated analysis produced by the TOA model showed that a combination of IPM and protective clothing could produce a win–win outcome throughout the range of price changes: neurobehavioural impairment and environmental contamination decreased while agricultural incomes increased or held steady (Antle et al, 1998c; Crissman et al, 2003).

Transforming Awareness and Practice: The Experience of EcoSalud

The unexpected severity of pesticide-related health problems and the potential to promote win–win solutions motivated the research team to search for ways to identify and break the pervasive cycle of exposure for the at-risk population in

Carchi. The EcoSystem Approaches to Human Health Program of IDRC (www.idrc.ca/ecohealth) offered that opportunity through support to a project called EcoSalud (*salud* means health in Spanish). The EcoSystem Approaches to Human Health Program was established on the understanding that ecosystem management affects human health in multiple ways and that a holistic, gender-sensitive, participatory approach to identification and remediation of the problem is the most effective manner to achieve improvements (Forget and Lebel, 2001).

The EcoSalud project in Carchi was essentially an impact assessment project designed to contribute directly to ecosystem improvements through the agricultural research process. The aims were to improve the welfare of the direct beneficiaries through enhanced neurobehavioural function brought about by reduced pesticide exposure, and to improve the well-being of indirect beneficiaries through farming innovation. The project design called for before-and-after measurements of a sample population that changed its behaviour as result of the intervention. Consistent with IDRC's EcoSystem Health paradigm, the intervention was designed to be gender sensitive and increasingly farmer- and community-led.

EcoSalud started by informing members of three rural communities of past research results on pesticide exposure and health impacts. To illustrate pesticide exposure pathways, we used a non-toxic fluorescent powder that glowed under ultraviolet light as a tracer (Fenske et al, 1986). Working with volunteers in each community, we added the tracer powder to the liquid in backpack sprayers and asked farmers to apply as normal. At night we returned with ultraviolet lights and video cameras to identify the exposure pathways. During video presentations, community members were astonished to see the tracer not only on the hands and face of applicators, but also on young children who played in fields after pesticide applications. We also found traces on clothing and throughout the house, such as around wash areas, on beds and even on the kitchen table. Perhaps more than other activities, the participatory tracer study inspired people to take action themselves.

People, in particular mothers, began to speak out at community meetings. The terms *el remedio* (the treatment) and *el veneno* (the poison) were often used interchangeably when referring to pesticides. Spouses explained that the need to buy food and pay for their children's education when work options were limited led to an acceptance of the seemingly less important risks of pesticides. They explained that applicators often prided themselves on their ability to withstand exposure to pesticides. As one young girl recounted (in Paredes, 2001):

> One time, my sister Nancy came home very pale and said that she thought she had been poisoned. I remembered that the pesticide company agricultural engineers had spoken about this, so I washed her with lots of soap on her back, arms and face. She said she felt dizzy, so I helped her vomit. After this she became more resistant to pesticides and now she can even apply pesticides with our father.

Despite stories such as this, many women became concerned about the health impacts of pesticides on their families. During one workshop, a women's group asked for disposable cameras to document pesticide abuse. Children were sent to spy on their fathers and brothers and take photos of them handling pesticides carelessly or washing sprayers in creeks. Their presentations led to lively discussions. The results of individual family studies showed that poisonings caused chronic ill-health for men and their spouses, and ultimately jeopardized household financial and social stability. Concern about the overall family vulnerability was apparent during community meetings, when women exchanged harsh words with their husbands over their agricultural practices that resulted in personal and household exposure to toxic chemicals. The men responded that they could not grow crops without pesticides and that the safer products were the most expensive. Communities called for help.

INIAP's researchers and extensionists in Carchi had gained considerable experience with farmer participatory methodologies for technology development, including community-led varietal development of late blight disease resistant potatoes. We know that such approaches can play an important role in enabling farmers to acquire new knowledge, skills and attitudes needed for improving their agriculture. INIAP built on existing relationships with Carchi communities to run Farmer Field Schools (FFSs), a methodology recently introduced to the Andes. In part, FFSs attempt to strengthen the position of farmers to counterbalance the messages from pesticide salespeople. As one FFS graduate said (in Paredes, 2001):

> Prior to the Field School coming here, we used to go to the pesticide shops to ask what we should apply for a problem. Then the shopkeepers wanted to sell us the pesticides that they could not sell to others, and they even changed the expiry date of the old products. Now we know what we need and we do not accept what the shopkeepers want to give us.

FFS have sought to challenge the most common of IPM paradigms that centres on pesticide applications based on economic thresholds and transfer of single element technologies within a framework of continuing pesticide use (Gallagher, 2000). In contrast, FFS programmes propose group environmental learning on the principles of crop health and ecosystem management as an alternative to reliance on curative measures to control pests. As a FFS graduate in Carchi noted (in Paredes, 2001):

> When we talk about the insects [in the FFS] we learn that with the pesticides we kill everything, and I always make a joke about inviting all the good insects to come out of the field before we apply pesticides. Of course, it is a poison, and we kill everything. We destroy nature when we do not have another option for producing potatoes.

In practice, the FFS methodology has broadened technical content beyond common understanding of IPM to a more holistic approach for improving plant and soil health. The FFS methodology adapts to the diverse practical crop needs of farmers, be they production, storage or commercialization. FFS ultimately aspires to catalyse the innovative capacity of farmers, as exemplified by how a graduate has improved cut foliage insect traps tested in his FFS (in Paredes, 2001):

> I always put out the traps for the Andean weevil, even if I plant 100 [bags of seed] because it decreases the number of adults. It is advantageous because we do not need to buy much of that poison Furadan. But I do use them differently. After ploughing, I transplant live potato plants from another field, then I do not need to change the dead plants every eight days.

In an iterative fashion, FFS participants conduct learning experiments on comparative (conventional *vs* IPM) small plots (about 2500m^2) to fill knowledge gaps and to identify opportunities for reducing external inputs while improving production and overall productivity. After two seasons, initial evaluation results in three communities were impressive. Through the use of alternative technologies, such as Andean weevil traps, late blight resistant potato varieties, specific and low toxicity pesticides, and careful monitoring before spraying, farmers were able to decrease pesticide sprays from 12 in conventional plots to seven in IPM plots while maintaining or increasing production (Barrera et al, 2001). The amount of active ingredient of fungicide applied for late blight decreased by 50 per cent, while insecticides used for the Andean weevil and leafminer fly (*Liriomysa quadrata*), that had commonly received the highly toxic carbofuran and methamidophos, decreased by 75 per cent and 40 per cent respectively.

Average yields for both conventional and IPM plots were unchanged at about 19t/ha but net returns increased as farmers were spending less on pesticides. FFS participants identified how to maintain the same level of potato production with half the outlay in pesticides and fertilizers, decreasing the production costs from about $104 to $80 per tonne. Because of the number of farmers involved in FFS test plots, it was difficult to assess labour demands in the economic analysis. Nonetheless, farmers felt that the increased time for scouting and using certain alternative technologies, such as the insect traps, would be compensated by decreased pesticide application costs, not to mention decreased medical care visits. A recent ex-post study that INIAP will publish in early 2004 has confirmed this trend at the level of individual farms of FFS graduates in Carchi (Barrera et al, in press).

In addition to the intensive six-month FFS experience, EcoSalud staff visited individual households to discuss pesticide safety strategies such as improved storage of pesticides, PPE, use of low volume nozzles that achieve better coverage with less pesticide, and more consistent hygienic practices. Based on widespread disinterest in PPE, we were surprised when participants began to request help in finding high quality personal protective equipment, that they said was unavailable at the dozens of local agrochemical vendors. EcoSalud staff found high quality PPE (mask, gloves, overalls and pants) through health and safety companies in the capital city, costing $34 per set, the equivalent of over a week's labour at the time. The project agreed to grant interest free, two-month credit towards the purchase price to those interested in buying the gear. Remarkably, 46 of the 66 participating families in three communities purchased complete packages of equipment. A number of farmers rented their equipment to others in the community in order to recuperate costs. Follow-up health studies are not complete, but anecdotal evidence is promising. As the wife of one FFS graduate who previously complained of severe headaches and tunnel vision due to extensive use of carbofuran and metamidophos said:

> Carlos no longer has headaches after working in the fields. He used to return home [from applying pesticides] and could hardly keep his eyes open from the pain. After the Field School and buying the protective equipment, he is a far easier person to live with (personal communication, farm family, Santa Martha de Cuba).

Complementary projects have supported follow-up activities in Northern Ecuador and elsewhere, including the production of FFS training materials (Pumisacho and Sherwood, 2000; Sherwood and Pumisacho, in press), the training of nearly 100 FFS facilitators in Carchi and nearby Imbabura, the transition of FFS to small-enterprise production groups and the establishment of farmer-to-farmer organization and capacity building. Concurrently, over 250 facilitators have been trained nationwide and hundreds of FFS have been completed. Recently, Ecuador's Ministry of Agriculture decided to include FFS as an integral part of its burgeoning national Food Security Program. Furthermore, in part due to the successful experience in Carchi, FFS methodology has subsequently spread to Peru, Bolivia and Colombia as well as El Salvador, Honduras and Nicaragua, where over 1500 FFS had been conducted by mid 2003 (LEISA, 2003).

Concluding Comments

Much conventional thinking in agricultural development places emphasis on scientific understanding, technology transfer, farming practice transformation and market linkages as the means to better futures. Consequently, the focus of research and interventions tends to be on the crops, the bugs and the pesticides, rather than the people who design, chose and manage practices. Recent experiences of rural development and community health, however, argue for a different approach (see for example, Uphoff et al, 1998; Norgaard, 1994; Latour, 1998; Röling, 2000). Of course, technologies can play an important role in enabling change, but the root causes of the ecosystem crisis such as in Carchi appear to be fundamentally conceptual and social in nature, that is, people sourced and dependent.

There is a general need for organizing agriculture around the development opportunities found in the field and in communities (van der Ploeg, 1994). Experience with people-centred and discovery-based approaches has shown promise at local levels, but ultimately such approaches do not address structural power issues behind complex, multi-stakeholder, socio-environmental issues, such as pesticide sales, spread and use.

The search for innovative practice less dependent on agrochemical markets needs to focus on the diversity of farming and the socio-technical networks that enable more socially and ecologically viable alternatives. Progress in this area would require a new degree of political commitment from governments to support localized farming diversity and the change of preconceived, externally designed interventions towards more flexible, locally driven initiatives. In addition, local organizations representing the most affected people must aim to influence policy formulation and implementation.

Our modern explanations are ultimately embedded in subtle mechanisms of social control that can lead to destructive human activity. The social and ecosystem crises common to modernity, evident in the people-pest-pesticide crises in the Northern Andes, are not just a question of knowledge, technology, resource use and distribution, or access to markets. Experience in Carchi demonstrates that approaches to science, technology and society are value-laden and rooted in power relationships among the diverse actors – such as farmers, researchers, industry representatives and government officials – that can drive farming practice inconsistent with public interest and the integrity of ecosystems. Solutions will only be successful if they break with past thinking and more effectively empower communities and broader civil society to mobilize enlightened activity for more socially and environmentally acceptable outcomes.

Incidence of Acute Pesticide Poisoning Among Female and Male Cotton Growers In India

Franceses Mancini, Ariena H. C. van Bruggen, Janice L. S. Jiggins, Arun C. Ambatipud and Helen Murphy

Introduction

Agriculture in South India is primarily a subsistence production system that involves 127 million cultivators and 107 million agricultural labourers. Crop productivity in the rainfed area, which includes more than 70 per cent of the cultivated land, is low and unpredictable (Department of Agriculture, 2002). The majority of the population is rural (74.3 per cent, Census 2001) and 34.7 per cent live below the international poverty level (World Bank, 2003).

During the Green Revolution, high yielding varieties of various crops were introduced into the farming systems to increase productivity. These varieties were significantly more susceptible to plant pests and diseases and, subsequently, the use of pesticides became more intense, increasing from 2330 kton during 1950–51 to 54,773 kton in 1990–91 (Directorate of Plant Protection, 2002, personal communication). Pesticides are largely applied to protect commercial crops. Cotton cultivation alone uses more than 60 per cent of the national consumption. The consequences of such indiscriminate use of pesticides have recently become a matter of public concern in India, following the publication of alarming information about the levels of pesticide residues in drinking water and soft drinks (CSE, 2003). Beside the consumers' risks stands the documented hazard to producers, who are directly exposed to chemical substances (Kishi et al, 1995; Murphy et al, 1999; Wesseling et al, 2001; Kunstadter et al, 2001). Agricultural labourers and

Incidence of acute pesticide poisoning among female and male cotton growers in India. *International Journal of Occupational and Environmental Health* 11(3), pp221–232 [In Mancini F. 2006. Impact of IPM Farmer Field Schools on Health, Farming Systems, the Environment, and Livelihoods of Cotton Growers in Southern India. PhD thesis, Wageningen University, Chapter 2, pp9–26.] Reproduced with permission.

farmers work in a highly unsafe occupational environment. The pesticides used largely belong to WHO category I and II (Highly Hazardous and Moderate Hazardous). Chemical products such as Aldicarb, Dieldrin and Paraquat that are banned in developed countries are still registered in India. Protective measures and equipment for safe handling and spraying of the pesticides are far from being adopted. Instead, people work barefoot, barehanded, wearing only short-sleeved cotton tee shirts and traditional sarongs (lungi). During an average spraying session, a farmer is directly exposed to pesticides for three to four hours at a time through leaking spray equipment, dripping plants and wind drift. Concentrated chemical products are mixed with water with bare hands. Farmer risky behaviour is not necessarily explained by a lack of awareness. On the contrary, farmers' level of knowledge on the health hazards of pesticides – even though partial and inexact – is in many cases higher than expected (Aragon et al, 2001; Clarke et al, 1997; Eisemon and Nyamete, 1990; Kishi, 2002). Training does little to change hazardous use of pesticides. For example, a programme conducted by Novartis to train farmers in the safe handling and use of pesticides in the Coimbatore District of Tamil Nadu, India, in 1992 failed to achieve substantial and sustainable changes in farmers' practices. Not only is protective equipment expensive, unavailable and cumbersome to use, but in the extreme hot weather conditions of the tropics protective gear is rarely used (Kishi et al, 1995). Therefore, educating farmers about the safe use of pesticides alone does not seem to be a viable solution to eliminate occupational risks.

To date, studies have focused on the adverse health effects occurring among people applying chemical products. However, the focus should also extend to those who play supportive roles in the pesticide applications: women and children. In India, the production of cotton is female-labour-intensive. Extremely time-consuming operations such as weeding are often performed by women and children during the peak of the spraying season when there are high residue levels in the fields. Other key female tasks are pesticide mixing with water and refilling the sprayers' tanks (Mancini, unpublished).

Pesticides are largely applied by low-income groups of people, marginal farmers and landless workers. Associated malnutrition and infectious diseases in these populations makes them more vulnerable to poisoning (London and Rother, 2000; WHO, 1990). The need to generate information about the social and gender implications of pesticide application has been well documented and recommended in a review of the health impacts of pesticides complied by Kishi (2005).

This study was engendered by the need to document the serious human health consequences of the indiscriminate use of pesticides on cotton in India. The intent was to focus on less-visible, but much exposed subjects: women and marginal farmers. Women perform secondary activities that have often been neglected in studies dealing with direct exposure. Marginal farmers are often engaged in professional spraying and therefore prone to continuous exposure.

Materials and Methods

Study objectives

In 2003, the European Union Food and Agriculture Organization, Integrated Pest Management (EU-FAO IPM) Programme for Cotton in Asia designed a participatory project that aimed to assess the frequency and severity of acute pesticide poisoning among cotton growers in Andhra Pradesh. For the last three years the programme has been operative in the state educating farmers in sustainable alternatives to pesticide use in Farmer Field Schools (FFSs). As part of the regular FFS curriculum, farmers were taught of the adverse effects of pesticides on human health and the environment. The assessment was conceived as a season-long special activity to be undertaken in three villages that had IPM[1] Farmer Field Schools.[2] The initiative aimed to measure the health effects of pesticide exposure in real time through direct farmers' documentation. Because previous studies focused on male farmers who apply chemical products, this study concentrated on women as respondents (for themselves and for their male relatives). This surveillance activity assisted farmers in generating information on:

- the frequencies and severities of acute pesticide poisoning occurring among male and female cotton farmers;
- the exposure of women performing supportive roles during spray operations;
- the vulnerability of low-income groups involved in pesticide application.

A second part of the assessment undertaken in 2004 in the same villages measured actual changes occurring in the health of the respondents, as a result of the participation in the cotton IPM FFS. Monitoring continued for several months, using the same reporting method as the study reported here. The data will be analysed against the baseline survey collected in 2003.

This paper represents the first part of the assessment conducted to estimate the effects on cotton growers' health of a chemical-based plant protection system.

Study area

The study was conducted in three cotton-growing villages. They were purposely selected immediately after the commencement of the FFS – on the basis of a high female (over 50 per cent) and marginal (< 1ha) farmer (55 per cent) participation predetermined by the FFS farmer selection process and the community's interest in the monitoring activity. The EU-FAO IPM Programme adopted the strategy of conducting one FFS per village, regardless of the village size. Therefore, there were 25 trained farmers per village, of which some were women. All the women who had participated in the FFS in the three villages joined the self-monitoring. Two of the villages (Sairedapalli and Srinagar) were located in Warangal District and one (Darpalli) in Mahaboobnagar District, Andhra Pradesh.

Andhra Pradesh is one of the nine major cotton-producing states of India. The rural population is 73 per cent of the total. Cotton is grown on 1.02 million hectares. The industrial production of cottonseed is also concentrated in the state. According to the 2001 census, Mahaboobnagar and Warangal districts have a total population of 3,077,050 and 2,818,832, respectively. Cotton is grown as the main crop during the rainy season (Karif) on 121,260ha in Warangal and 22,697ha in Mahbubnagar.

Darpalli is a small village populated by marginal native farmers (721 inhabitants). The area under cotton was 45 hectares. The level of education among the people was found to be very low (in 1997, 70 per cent of the rural people in the state were not literate). In contrast, migrant communities, who moved from the state coastal area in search of fertile lands to cultivate, mainly inhabited Srinigar and Sairedapalli villages. The villages had respectively 3108 and 1038 inhabitants; the area under cotton was 500ha and 122ha. Those villages could be considered better off in that they had more education and wealth.

Training of enumerators and farmers

The study involved three FFS facilitators trained by the EU-FAO IPM Programme for Cotton in Asia in season-long (six months) residential Training of Facilitators (ToF) on IPM. In addition to the technical knowledge, the ToF provides a solid background about adult non-formal education and enables facilitators to conduct Participatory Action Research with farmers. In order to coach the self-health monitoring, three FFS facilitators were also taught how to identify the signs and symptoms of acute pesticide poisoning. Emphasis was given to the need for establishing clear correlations between illness and exposure to pesticides. Minor adaptations to the specific study requirements were made to the reporting format and method developed by Murphy et al (1999, 2002).

During the initial FFS sessions, three facilitators trained the farmers who had volunteered to participate in the monitoring. The forms to be used were field tested with 20 respondents to correct for any potential misunderstandings of the reporting procedures as well as misconceptions about the signs and symptoms. During the four months of the assessment, the project staff provided constant coaching to the farmers and the facilitators. A mid-season review meeting was also organized two months from the start. A simple analysis of the forms was done together with the farmers at the end of the season in a final workshop.

Period and procedure

The actual reporting started in the second month of the cotton-growing season when pesticides are first applied to the young plants, in August 2003, and lasted until December 2003. Women farmers (n = 50) attending the FFSs, organized in their respective villages, filled in health-monitoring forms after potential exposure to a variety of pesticides. In addition to self-reporting their own signs and symptoms of acute poisoning, the women each interviewed one male family member (n = 47) who had applied pesticides. Respondents were asked to fill in a form after every potential pesticide exposure regardless of whether or not they had experienced an adverse effect. Forms were filled in as a result of any of the following circumstances:

- spraying pesticides in the field;
- mixing chemical solution and refilling spray tanks;
- working in field sprayed within the same day.

Only the signs and symptoms that occurred during the working session or within 24 hours after exposure were recorded. At each FFS meeting the forms were reviewed.

Format

The reporting format was pictorial to facilitate participation among those who were not literate (Figure 5.1). Facilitators provided the necessary assistance to review the forms throughout the monitoring.

The form allows for the reporting of the following:

- a list of 18 signs and symptoms (S&S) of acute pesticide poisoning (see Table 5.2);[3]
- type of chemical products used;
- quantity of chemical products used (ml formulated product/Lt water);
- hours spent in performing the operation;
- hours extra-respite taken due to illness;
- number of sick days not worked as a consequence of the illness;
- use of medical treatments and home-made remedies;
- operation performed.

The following socioeconomic parameters were collected in separate interviews from each respondent: Age, Gender, Formal education, Landholding, Profession and Income level. A total of 97 farmers, 50 women and 47 men, participated in the self-health monitoring (Table 5.1). All the women participating in the FFSs in the

Table 5.1 *Distribution of respondents among the village*

	Women (respondents)	*Men (indirect reporting)*	*Total*
Darpalli	25	23	48
Sairedapalli	14	14	28
Srinagar	11	10	21
Total	50	47	97

three villages were involved in the self-monitoring. As a result of the purposive selection of the villages, the sample included 70 per cent of small farmers (<2ha).

Twitching of eyelids	Systemic/neurotoxic	2
Vomiting	Systemic/neurotoxic	2
Loss of consciousness	Systemic/neurotoxic	3
Seizure	Systemic/neurotoxic	3

Scoring system

The forms were assigned to four categories according to the signs and symptoms (S&S) reported following Murphy's method (Murphy et al, 2002). Local effects were considered consequences of mild poisoning and rated in category 1. In the same category were some systemic or neurotoxic effects that are ill-defined (headache, dizziness, difficulty breathing) and effects that could be related to or confused with environmental factors such as heat exposure (excessive sweating, excessive salivation). The other neurotoxic effects such as nausea and vomiting, which might reflect cholinesterase depression, were classified in category 2 or moderate poisoning. Category 3 included loss of consciousness and seizure as effects of severe poisoning. Each form was assigned with a final value (severity class) equivalent to the highest category marked. Forms with no signs and symptoms marked were assigned with severity class 0 and classified as an asymptomatic event. Forms containing only category 1 effects were classified as mild acute poisoning events (Class 1). If at least one effect belonging to category 2 was included, the forms were classified as moderate poisoning events (Class 2). Finally, if one of the effects of category 3 was marked, the forms were considered an example of severe acute poisoning (Class 3). In addition to the severity class, the total sum of signs and symptoms reported in each form was also considered as an indicator of poisoning. For each form two values were therefore entered in the database as severity indicators.

- severity class;
- total number of S&S reported (#S&S).

Data analysis

Linear trend analysis (frequencies analysis and chi-square test) was performed to describe pairs of variables (men versus women and small versus large). The severity class and the #S&S were analysed in relation to the exposure variables. Multivariate analysis (multiple linear regression) was used to assess the contribution of each independent variable (Age, Gender, Formal education, Exposure Time, Pesticide Toxicity, Volume, Operation, Landholding, Income, Profession) to the severity values. Further analysis on the combination of signs and symptoms per spraying event will be performed on the complete data set at the end of the second season collection.

Results

Characteristics of the respondents

The average ages of the reporting women and interviewed men was respectively 36.5 and 37 years. The distribution by age categories is given in Table 5.3. Almost half of the respondents fell into the class 'marginal' (< 1ha) (Table 5.3). Forty-one per cent of the farmers lived below the national poverty level (10 rupees a day or 1$ per 4–5 days).

Spraying operations

Individual spraying sessions recorded in four months of monitoring totalled 392. On average, farmers filled out one form per month. However, 69 forms have been

Women	22	11	12	5
Men	19	13	7	8

discarded due to incomplete information on the pesticides used. The distribution of the discarded forms could not be analysed and therefore biases introduced by the selection cannot be excluded. The women self-reported on 165 events and reported on 158 spraying sessions that were performed by their male relatives. The total number of forms per farmer did not reflect the individual field spraying frequency, which was separately recorded. In Darpalli village the average number of sprays for the cotton season was 5.9 (range 2–15), in Sairedapalli it was 6.4 (range 1–11) and in Srinagar 11 (range 5–14).

In the case of the women, the health forms were filled in after mixing concentrated chemicals with water and filling spray tanks (47 per cent), mixing and subsequently working in the field (24 per cent), working in a recently sprayed field (17 per cent), applying pesticides (9 per cent) and others (3 per cent). The application of pesticides referred to the spreading of phorate granules (organophosphate, WHO 1A hazard class) on maize and chilli plants.

Men's forms were filled after spraying pesticides (75 per cent), spraying and subsequently working in the field (22 per cent) as well as mixing concentrated chemicals with water and filling spray tanks (4 per cent). The average working session lasted 4h 36m for men and 4h 24m for women, an average volume respectively of 238 and 242 litres, containing 212 and 190mg of active ingredient was applied. During the study, participatory observations were conducted to better describe the gender roles of the pesticide application task. An example is given in the specific section at the end of the article.

Twenty-six types of chemicals (Table 5.4) were used. Products belonging to the organophosphate family were used in 47 per cent of the spraying events. Endosulfan (organochlorine) alone was used in 135 of the sprays.

Health effects

Reported signs and symptoms

Out of the 323 reported events 16.4 per cent were asymptomatic, 39 per cent led to mild poisoning, 38 per cent to moderate and 6 per cent to severe. Participatory evaluation is sometimes subjected to strategic bias introduced by the respondents themselves, who are centrally involved in the risk behaviours. In the case of this study, such bias would have led to an over-reporting of the health effects. In order to assess the validity of the respondents' reporting, three symptoms (excessive tearing, excessive salivation and tremor) specific to organophosphate (OP) exposure were used as dummy symptoms. Tremor was associated with OP exposure in 83 per cent of the cases, excessive tearing in 62 per cent and excessive salivation in 60 per cent. According to the respondents, endosulfan (organochlorine) was responsible for 28 per cent of the excessive tearing, 12 per cent of excessive salivation and 8 per cent of tremor (1 case). The remaining cases were explained by exposure to chloro-nicotinyl, a relatively new chemical class of systemic insecticides that act on the central nervous system. Organochlorines do not stimulate glands and therefore are not expected to cause the above mentioned symptoms. However, the relatively

* The WHO hazard classification refers to the formulated chemical products. The classification of the formulations was based on toxicity data obtained on that formulation by the manufacturer. In the cases in which this was not available, the values were calculated on the basis of the LD_{50} oral or dermal toxicity using WHO conversion tables (IPCS, 2000–2002). 1A = extremely hazardous, 1B = highly hazardous, 2 = moderately hazardous, 3 = slightly hazardous, U = unlikely to present acute serious hazard in normal use.

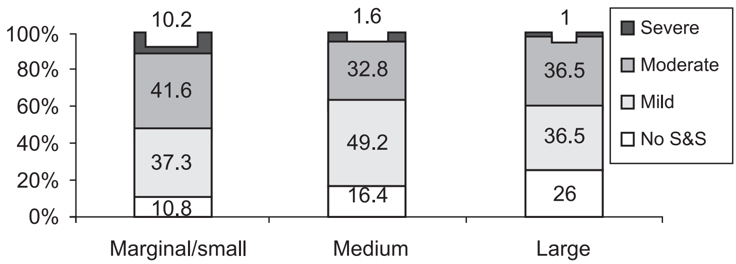

Figure 5.2 *Distribution of acute pesticide poisoning severity classes by landholding classes*

high association of the symptoms with the use of endosuifan, imidachloprid and acetamiprid but not with the use of any other pesticide is striking. No association between the three symptoms and the use of pyretroids, botanical and inorganic components was reported.

The frequency of spray-session illness events are significantly different depending on landholding status (chi square significant at $p < 0.0001$). The incidence of severe poisoning was 10 times higher among marginal farmers than larger landholding farmers (Figure 5.2). Of the marginal and small landholding farmers, 10.2 per cent suffered major effects. The distribution in Figure 5.3 shows that marginal and small farmers experienced more signs and symptoms than those who owned medium-sized and large farms. Average exposure time and pesticide toxicity were calculated for the sub-samples marginal, medium and large farmers, but the values did not explain this result. The level of formal education can partially explain the finding. Non-literate farmers experienced an average 4,8 #S&S and a severity class of 2,9 against respectively 2,4 and 2,2 for farmers educated to secondary school level. The values for farmers educated above secondary school level were remarkably lower (0,6 #S&S and 1,3 severity class), however, the sample was too small (4 farmers) to be considered representative.

The higher vulnerability of small and poor farmers could also be related to their general health conditions and to a cumulative effect of prolonged occupational exposure over the years. An important factor that could have played a role in diversifying exposure among groups is the application method, not considered in this study. Wealthier farmers are often in the position to afford safer equipment for applying pesticides. It worth noticing that 70 per cent of the asymptomatic events occurred among large and medium farmers. The higher incidence clearly reported calls for confirmation through an appropriate research design.

The village-wise analysis also showed a higher illness incidence among farmers in Darpalli than in the other two villages. Loss of consciousness and seizure had been recorded only among the poor community of this village. In the case of the two villages in Mahaboobnagar, the effects on the health of the reporting farmers were mild. The results of a separate ongoing analysis of the labour organization within the same households might provide additional information to cross-check

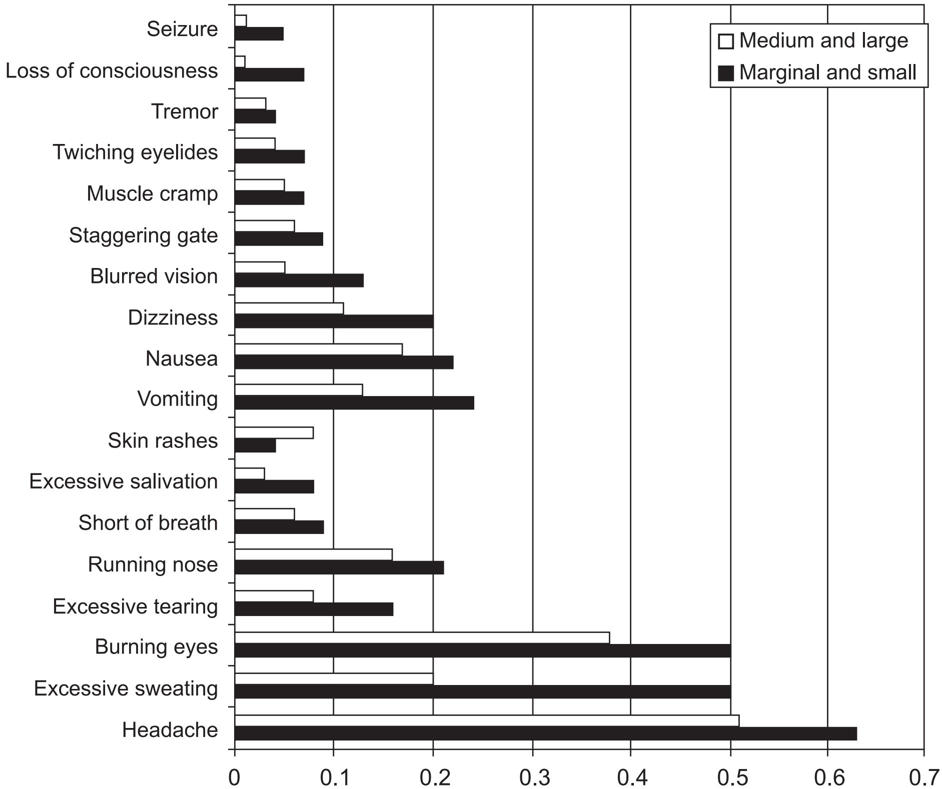

Figure 5.3 *Distribution of acute poisoning signs and symptoms by landholding classes*

individual exposure time to pesticides and explain some of the difference. A village effect might have been introduced in the reporting by the fact that each facilitator was operative in only one village.

The gender segregated analysis showed no significant differences in the distribution of signs and symptoms between men and women. Also, the severity class was not significantly correlated with the gender of the respondents. The health effects experienced by the women were comparable to the ones experienced by men. No significant correlation was found between severity class and age. However, the reader is reminded that children were not included in the surveillance. These results confirm the hypothesis that women are seriously exposed to pesticide contamination.

Severity class and total number of S&S (#S&S) versus exposure variables
Each exposure was described by five variables:

- *Pesticide toxicity*: toxicity of the formulated chemical product classified according to the WHO Hazard classes. Pesticides belonging to the WHO class 1a ('extremely hazardous') scored 1 point, class 1b ('highly hazardous') points 2, class II ('moderately hazardous') points 3 and class III ('slightly hazardous') points 4. Pesticides unlikely to present acute hazard in normal use (class U) were assigned with a score of 5 points.

- *Exposure time*: the duration in hours of the working session.
- *Volume*: the final volume of the spraying solution expressed in litres.
- *Operation*: the activity performed during the working session.
- *Profession*: The variable referred to whether the respondents were hired to apply pesticides in others' fields, in addition to their own.

The mean/median of the #S&S associated with the different categories of pesticide toxicity, the severity class and the exposure time is given Table 5.5. The distribution of the severity class by gender across operation performed (Table 5.6) showed that spraying and mixing were key exposure activities with a very similar incidence of severe poisoning. During mixing operations, the respondents prepared chemical solutions in rapid succession at close time intervals. Between mixing sessions, the respondents

were present in the field. The same activities (mixing), when associated with fieldwork afterwards, led to a slight shift of the distribution towards a higher degree of severity. 'Mixing' and 'spraying' tasks had an average duration of 3.5 and 3.8 hours respectively. The same operations combined with fieldwork lasted 6.7 hours (mixing and field work) and 7 hours (spraying and fieldwork). Prolonged exposure led eventually to the development of more severe illness. Fieldwork alone did not cause any severe or moderate poisoning. This may be explained by the absence of direct contact with the concentrated chemical. To determine the contributions of individual factors, severity class and #S&S, were regressed (Table 5.7) on the five exposure variables, the three social variables (Gender, Age, Formal education) and three economic variables (Landholding, Income, Profession). The highest R^2 was found for the model that incorporated Education, Landholding, Profession, Exposure Time and Toxicity.

Participant observation of a pesticide spraying session

In order to corroborate the finding on women's exposure to pesticide, the first author observed some spray sessions in Darpalli village. Table 5.8 refers to a typical hour of work during which wife and husband were continuously present in the field. The pesticide mixture was prepared by the woman, without any sort of protective equipment. The concentrated product was mixed barehanded and every 7–9 minutes the tank was refilled, for a total of six refillings an hour. The session lasted three hours. Throughout the session the woman followed the man who was spraying the mixture. Repeated exposure of the two operators was evident. The average reporting session of the female respondents for 'mixing of pesticides' was

Table 5.8 *Time schedule of one hour spraying session (participant observation)*

Time	*Operator**	*Operation*	*Comments*
8.00 – 8.10	W	Preparation of spray solution	Bare hand
8.10 – 8.20	M	Spraying	Bare hand and foot
	W	Preparation of refilling	Legs and back wet
8.20 – 8.21	W	Refilling	Mixing with bare hand
8.22 – 8.29	M	Spraying	Strong smell of chemical spreads in the air
	W	Preparation of refilling	
8.30	W	Refilling	
8.30 – 8.40	M	Spraying	Both have to walk across the sprayed area to reach unsprayed areas. Contact with solution dripping from the plants
	W	Preparation of refilling	
8.41	W	Refilling	Rinsing of the chemical measuring container with bare hand
8.41 – 8.50	M	Spraying	Woman works in the field
	W	Preparation of refilling	
8.51	W	Refilling and moving to another field	
8.55 – 9.00	M	Spraying	
	W	Preparation of refilling	

* W = woman, M = man

likely to include 26–28 brief exposures to the concentrated products and a prolonged air exposure to the freshly applied mixture.

Medical assistance

Regardless of the seriousness of the illness, farmers sought medical advice in only 8 per cent of cases. Homemade treatments were taken in 70 per cent of the cases; no action was taken in the remaining cases. In rare cases, a few hours of extra rest (1.41 for women and 1.38 for men) were necessary before resuming the work. In 7 per cent of the cases, a full day's rest was recorded – a total of 23 sick days for the all participants during the four-month reporting period. This percentage is similar to the total number of severe cases reported (5.9 per cent).

This suggests that the use of sick days as an indicator might lead to an underestimation of the extent of pesticide poisoning.

Farmers' workshop

Farmers consolidated and discussed the results in a final workshop. A colour-based code, suitable for a non-literate population was used to score the forms following the same scoring procedure as described in this article. Participants attributed a final severity class to each form and analysed its frequency. The findings led to the farmers' realization of the serious health consequences associated with the irrational use of pesticides. The monitoring was conducted as part of the FAO Cotton IPM Programme to support the adoption of viable and socially acceptable alternatives to the pesticides.

Discussion

The study documented the serious consequences of the indiscriminate use of pesticides on farmers' health in India and specifically on women field helpers. The health surveys reviewed by Kishi in 2005 pointed out that the existing world data on poisoning refer mainly to young male subjects applying pesticides. There are also some examples that investigated the exposure of women who performed the same operations (Murphy et al, 1999; Kimani and Mwanthi, 1995; Trivelato and Wesseling, 1992). However, women in developing countries are prone to other ways of exposure because, through their supportive roles, they are often involved in the chemical application process (London et al, 2002). Few studies have mentioned this aspect and none have ever estimated the ill effects (Rother, 2000). The current survey addressed this information gap by focusing on the adverse effects developed by two target groups, women and marginal farmers, after they performed operations at risk of contamination.

The current self-monitoring has shown no differences between the degree of illness experienced by women and men. Whether this is related to the fact that women were reporting both on themselves and their husbands is not entirely clear. Nevertheless, women were reporting significant health effects. Typically female tasks, such as mixing concentrated chemical products and refilling spraying tanks, are key exposure activities, which have been proved to be as hazardous as the direct pesticide application itself.

Ten per cent of the spray sessions were associated with three or more neurotoxic/systemic signs and symptoms, which is the functional definition of acute poisoning used in Indonesia by Kishi et al (1995). The adverse effects on the central and the peripheral nervous systems were typical of poisoning caused by organophosphates (Keifer, 1997), these products were used in 47 per cent of the applications. Damage caused by cholinesterase-inhibitors with organophosphates can become permanent (McConnell and Magnotti, 1994; Miranda et al, 2002; Rosenstock et al, 1991; Wesseling et al, 2002). Although 6 per cent of the spray sessions were associated with serious neurotoxic effects, none sought medical care or were hospitalized. On the contrary, farmers rarely stop working for more than a day. This finding confirms the serious underestimation of statistics based on official medical records (Keifer, 1996; Murray, 1994).

Low-income marginal farmers are more often subjected to severe poisoning than landlords. Smallholders and landless people often apply pesticides throughout the season as waged. Repeated exposure, in addition to malnutrition and other diseases, might explain the higher vulnerability of these groups (WHO, 1990; Repetto and Baliga, 1997). Indeed, pesticide toxicity and exposure time were positively correlated to the extent to which symptoms were experienced in this survey, while formal education and landholding were negatively correlated to this measure of ill health. Yet, only 29 per cent of the variation in symptom severity could be explained by these factors.

However, more research is needed on factors contributing to the health of people exposed to pesticides, in particular high-risk groups that are rarely included in health surveillance on pesticides' effects (Moses, 1993; Zham and Blair, 1993).

The survey aimed primarily to raise farmers' awareness on the seriousness of the poisoning occurring in the villages. It also aimed to quantify the problem by direct farmers' reporting. The method has some limitations. Murphy's article (Murphy et al, 2002) includes a detailed strength and weakness analysis of the method. We have reported here only those aspects which are relevant to this survey. Since signs and symptoms of acute poisoning are non-specific, the health data generated can be taken only as estimates. Whether the women over- or underreported the true extent of the problem cannot be determined without biomarkers. A gender bias related to the difference in reporting methods between women and men could also have been introduced. Self-monitoring data would need to be backed up by clinical data and blood sample analyses, such as cholinesterase depressions. Another issue is that respondents belonging to the same village had close interactions. This may have introduced a systematic bias yielding homogeneity of reporting. Finally, the method cannot appreciate the chronic consequences of prolonged exposure to pesticides. Relevant in the case of women are the long-term effects on the reproductive system that can lead to abortions, still births, neonatal deaths and congenital defects (Restrepo, 1990; Taha and Gray, 1993; Zhang et al, 1992; Rojas et al, 2002). Nevertheless, a study conducted in India has shown that female cotton workers experienced the same long-term consequences of exposure to pesticides (Rupa et al, 1991). Our research concerned only adult respondents (above 18 years) and no age factor on the severity of the poisoning was found. However, the Pan American Health Organization estimated that between 10–20 per cent of all poisoning cases involve children. The cottonseed industry in India employs thousands of female children from 7 to 14 years old to manually cross-pollinate the plants. There is a need to investigate the impact on children exposed to pesticides. The survey covered one cotton season and therefore the number of records is limited. A second period of data collection is, however, scheduled for 2004 with the same respondents to estimate changes in farmers' health induced by the cotton IPM FFS.

The extent of pesticide poisoning among farmers and workers in developing countries is worrying (Kishi, 2005). In the extreme hot weather of the tropics, protective gear does not seem to be a viable solution to eliminate occupational risks. Farmers' education on the pesticide hazard alone has not achieved significant results. The solution seems to be in the replacement of pesticides with non- or less toxic alternatives. One example of such alternatives can be found in the Integrated Pest Management approach.

Acknowledgements

The authors are grateful to the EU-FAO IPM Programme for cotton in Asia for providing necessary financial help in carrying out this project. They thankfully acknowledge the valuable reviews and comments of the following: Peter Ooi, Palantswamy Pachagounder and Gerd Walter-Echols, EU-FAO IPM Programme; Peter Kenmore and Harry van der Wulp, Global IPM Facility; Aad Termorshuizen, Wageningen University and Research Centre. Special recognition is due to the Indian farmers and facilitators who participated in this project.

Notes

1 Integrated Pest Management (IPM) is based on preserving natural enemies and growing healthy crops to control pests.
2 Farmer Field School (FFS) is an adult educational approach to empower farmers, developed in Indonesia in the early 1990s.
3 Developed by Keifer (1996) and adopted by Murphy et al (2002). The list is given in Table 5.2.

Agroecology and Sustainability

6

The Properties of Agroecosystems

Gordon R. Conway

Introduction

Agroecosystems are ecological systems modified by human beings to produce food, fibre or other agricultural products. Like the ecological systems they replace, agroecosystems are often structurally and dynamically complex but their complexity arises primarily from the interaction between socioeconomic and ecological processes. Hitherto studies of agroecosystems have tended to concentrate on the flows and cycles of energy and materials (see reviews in Frissel, 1977; Loucks, 1977; Lowrance et al, 1984). While these have furnished valuable insights they have captured only a part of agroecosystem complexity and have had relatively little impact on the theory and practice of agricultural development. In this chapter I suggest that agroecosystems can be characterized by a limited set of dynamic properties that not only describe their essential behaviour, but can be used normatively as criteria of agroecosystem performance and hence can be employed in the design and evaluation of agricultural development projects, at all levels of intervention.

Agroecosystems as Systems

Although the concept of the ecosystem is long standing (Tansley, 1935), it is often difficult to identify and characterize ecosystems in nature. Their boundaries are frequently obscure and sometimes ecosystems appear to be no more than random clusterings of weakly interacting populations. Indeed, there has been some dispute as to whether natural ecosystems are true cybernetic systems, that is, have clearly defined goals and are steered towards realizing these goals by pervasive feedback control loops and communication networks (Engelberg and Boyarsky, 1979; McNaughton and Coughenour, 1981; Jordan, 1981; Knight and Swaney, 1981; Patten and Odum, 1981). Nevertheless, there can be little doubt that the transformation of ecosystem to agroecosystem produces well-defined systems of a cybernetic nature.

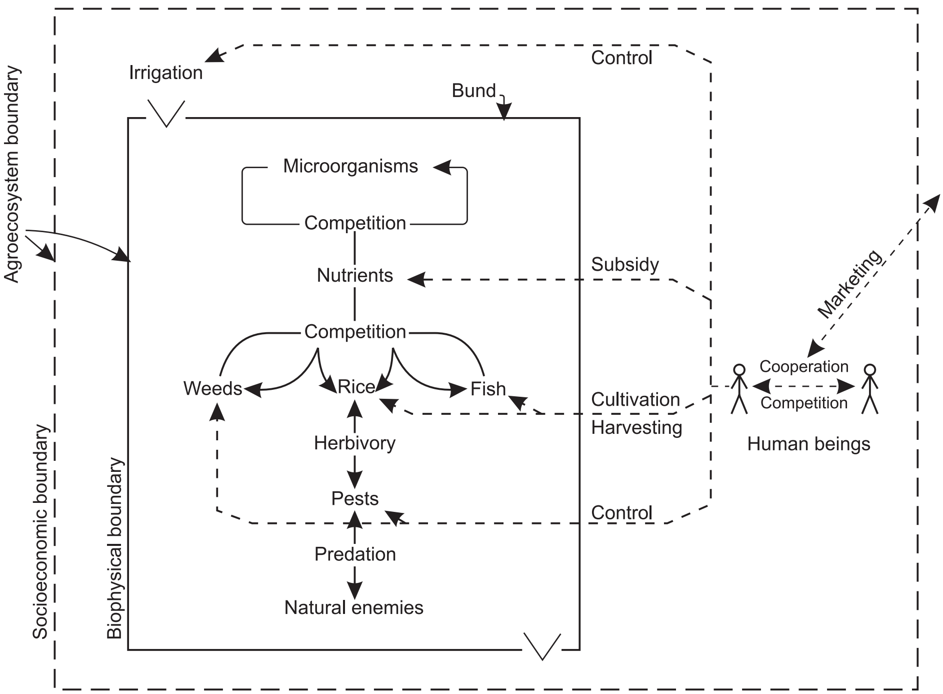

Figure 6.1 *The rice field as an agroecosystem*

In the transformation the great diversity of wildlife in the original natural system is reduced to a restricted assemblage of crops, pests and weeds (Figure 6.1). There is a strengthening of the biophysical boundary of the system, a bund is created around the rice field, for example, which makes the boundary less permeable. The basic ecological processes – competition, herbivory and predation – still remain, but these are now overlaid and regulated by the agricultural processes of cultivation, subsidy, control, harvesting and marketing. Recognizable system goals become apparent that are sought through human social and economic cooperation and competition. One consequence is that the system boundary acquires a socioeconomic dimension. It is this new complex agro–socio–economic–ecological system, bounded in several dimensions, that I call an agroecosystem. At least in cybernetic terms, an agroecosystem defined in this way is more similar to an individual organism than it is to a natural ecological system.

The most widely recognized agroecosystem is the crop field conceptualized in Figure 6.1, or the livestock paddock. But if agroecosystems are defined so as to include both ecological and socioeconomic components, then we can envisage a classical hierarchy of such systems (Figure 6.2). At the bottom of the hierarchy is the agroecosystem comprising the individual plant or animal, its immediate microenvironment, and the people who tend and harvest it. Examples where this exists as a recognizably distinct system are the lone fruit tree in a farmer's garden or the

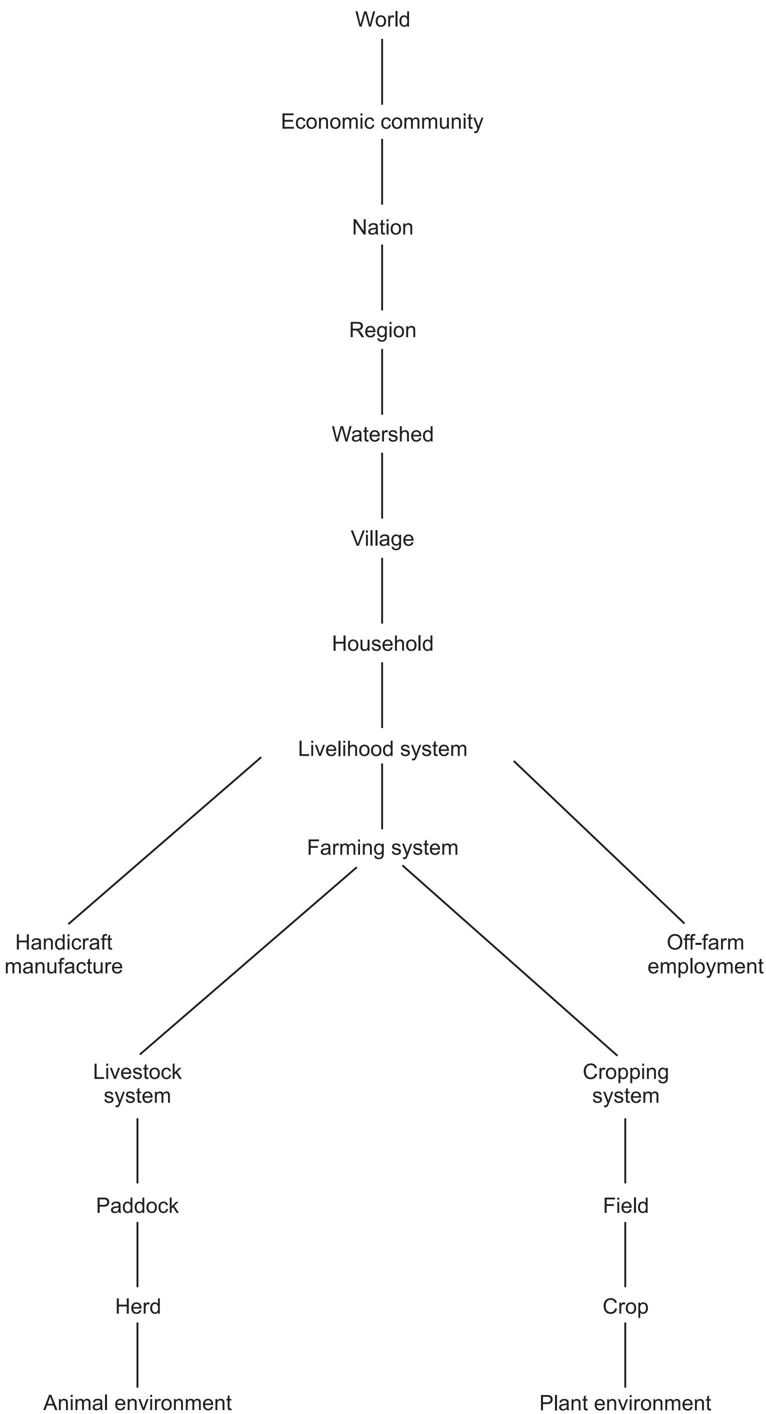

Figure 6.2 *The hierarchy of agroecosystems*

milk cow in a stall, but it is possible to think of the individual plant in a crop population or the animal in a herd in this way. The next level is the field or paddock and the hierarchy continues upwards in this way, each agroecosystem forming a component of the agroecosystem at the next level. Near the top is the national agroecosystem composed of regional agroecosystems linked by national markets, and above that the world agroecosystem consisting of national agroecosystems linked by international trade.

Systems theory holds that the behaviour of higher systems in such a hierarchy is not readily discovered simply from a study of lower systems, and vice versa (Simon, 1962; Whyte et al, 1969; Milsum, 1972; Checkland, 1981). This has important consequences not only for analysis but for agricultural policy and planning. It implies that agricultural development cannot be based solely, or largely, on genetic engineering, or macro-economic policy, or even on farming systems research. Each level in the agroecosystem hierarchy has to be analysed and developed both in its own right and in relation to the other levels above and below, and this totality of understanding used as the basis of development. To achieve this is a difficult task but is greatly helped by a common approach to analysis and, in particular, a set of well-defined common properties for each level in the hierarchy that can be related to each other, within and between levels.

Agroecosystem Properties

Individual organisms can be characterized by the basic properties of growth and reproduction, maintenance and survival (Table 6.1). In cybernetic terms the 'goal' of an organism is increased fitness and this is achieved through one of a variety of combinations of high and low values of these properties. The particular combination present in an organism can be regarded as its life history strategy (MacArthur and Wilson, 1967; Grime, 1979). For natural populations, communities and ecosystems it is possible to define a similar set of system properties, consisting of (1) productivity, (2) stability (constancy) and (3) resilience (as defined by Holling, 1973). In each case these refer to the numbers or biomass of individuals or species, or some combination of these measures. Unlike individual organisms, though,

Table 6.1 *The properties of ecological systems*

	Individual	*Population*	*Community*	*Ecosystem*	*Agroecosystem*
'Goal'	Fitness	(Fitness)	—	—	Social value
System properties	Growth Reproduction Maintenance Survival		Productivity Stability Resilience		Productivity Stability Sustainability Equitability

Source: Conway, 1982b.

there is no obvious 'goal' for a population, community or ecosystem and these properties are simply the outcomes of co-evolution.

However, for agroecosystems a clear goal, in the form of increased social value, is once again apparent. Social value, defined here in terms consistent with classical welfare economics (see, for example, Layard and Walters, 1978), is a function of the amounts of goods and services produced by the agroecosystem, their relationship to human needs (or happiness) and their allocation among the human population. Like fitness, it has a time dimension, humans seeking not only increased benefits in the immediate future but also a degree of security over the longer term. Social value thus has several measureable components: the present production, its likely level over a future time horizon and its distribution among the human population. Each agroecosystem, at each level in the hierarchy, has a social value and it also follows that one form of agroecosystem may have a greater social value than another (in much the same way that one organism is fitter than another) and hence may be selected for by a human population.

While welfare economics provides a good theoretical basis for defining social value, the concepts involved are of limited practical value. Production frontiers, utility and welfare functions are difficult, if not impossible, to measure. In practice, therefore, an assessment of an agroecosystem's performance has to be made not in terms of the theoretical goal but in relation to those key system properties that contribute most directly to realizing the goal. I have suggested there are four such primary agroecosystem properties – productivity, stability, sustainability and equitability (Conway, 1982a, 1982b). The first three approximately correspond to the properties of natural ecological systems; the principal distinction is that each is defined in terms of the valued output of the system and hence may be measured in both biological and socioeconomic units (Altieri and Anderson, 1986). The fourth property, equitability, has no direct counterpart in natural ecological systems.

Productivity

Productivity is defined here as the output of valued product per unit of resource input. Common measures of productivity are yield or income per hectare, or total production of goods and services per household or nation, but a large number of different measures are possible, depending on the nature of the product and of the resources being considered. Yield may be in terms of kilograms of grain, tubers, leaves or of meat or fish or any other consumable or marketable product. Alternatively, it may be converted to value in calories, proteins or vitamins or to its monetary value at the market. Frequently, the valued product may not be yield in conventional agricultural terms. It may be employment generation, or an item of amenity or aesthetic value or one of a wide range of products that contribute, in ways that are difficult to measure, to social, psychological and spiritual well-being (Chambers, 1986).

The three basic resource inputs are land, labour and capital. Strictly speaking, energy is subsumed under land (solar energy), labour (human energy) and capital (fossil fuel energy). Similarly, technological inputs, such as fertilizers and pesticides, are components of capital, but both energy and technology can be treated, for many purposes, as separate inputs.

Each possible combination of output and input can be regarded also as measures of efficiency of production when two or more agroecosystems are compared (NAS, 1975; Spedding, 1979). Assessments may be made of productivity at different levels in the hierarchy of agroecosystems, of the field, farm, village, watershed, region or nation. Also comparisons may be made between agroecosystems of different types (e.g. between a cornfield and a cottonfield, or a lowland and an upland village). Over time productivity may rise, fall or remain static.

Stability

Stability may be defined as the constancy of productivity in the face of small disturbing forces arising from the normal fluctuations and cycles in the surrounding environment. Included in the environment are those physical, biological, social and economic variables that lie outside the agroecosystem under consideration. The fluctuations, for example, may be in the climate or in the market demand for agricultural products. Productivity may be defined in any of the ways described above and its stability measured by, say, the coefficient of variation in productivity, determined from a time series of productivity measurements. Since productivity may be level, rising or falling, stability will refer to the variability about a trend.

Sustainability

Sustainability is defined as the ability of an agroecosystem to maintain productivity when subject to a major disturbing force. The actual or potential disturbance may be caused by an intensive stress, where stress is defined as a frequent, sometimes continuous, relatively small and predictable disturbing force which has a large cumulative effect. Salinity, toxicity, erosion, indebtedness or declining market demand are examples of such forces. Alternatively, the disturbance may be caused by a shock, defined here as an infrequent, relatively large and unpredictable disturbing force which has the potential of creating an immediate, large disturbance or perturbation. Examples of shocks include a rare drought or flood, or a new pest or the sudden rise in an input price, such as that of oil in the mid-1970s.

Following a stress or shock the productivity of the agroecosystem may be unaffected, or may fall and then return to the previous level or trend, or settle to a new lower, or sometimes higher, level or may disappear altogether. Various measures of sustainability are available: they include the inertia (resistance), elasticity, amplitude, hysteresis and malleability of the agroecosystem in response to a disturbing force (Orians, 1975; Westman, 1978). Sustainability thus determines the persistence or durability of an agroecosystem's productivity under known or possible conditions. It is a function of the intrinsic characteristics of the agroecosystem, of the nature and strength of the stresses and shocks to which it is subject, and of the human inputs that may be introduced to counter these stresses and shocks.

A ubiquitous input is the subsidy, often in the form of a fertilizer application, intended to counter the stress of repeated harvesting. Sustainability is maintained only by renewed fertilizer application. Another common form of input is a control agent; for example, a pesticide to counter pest or disease attack. Again, sustainability may necessitate repeated pesticide applications, but an alternative strategy may be the introduction of a biological control agent, such as a parasitic wasp, which may so permanently alter the intrinsic sustainability characteristics of the agroecosystem as to obviate the need for further intervention. In some situations inputs may become part of the problem because, directly or indirectly, they generate stresses and shocks. Frequent pesticide applications, for example, may elicit pesticide resistance and hence growing pest attack. The number of applications may have to be increased to sustain productivity, but in the end productivity may still collapse (Figure 6.3).

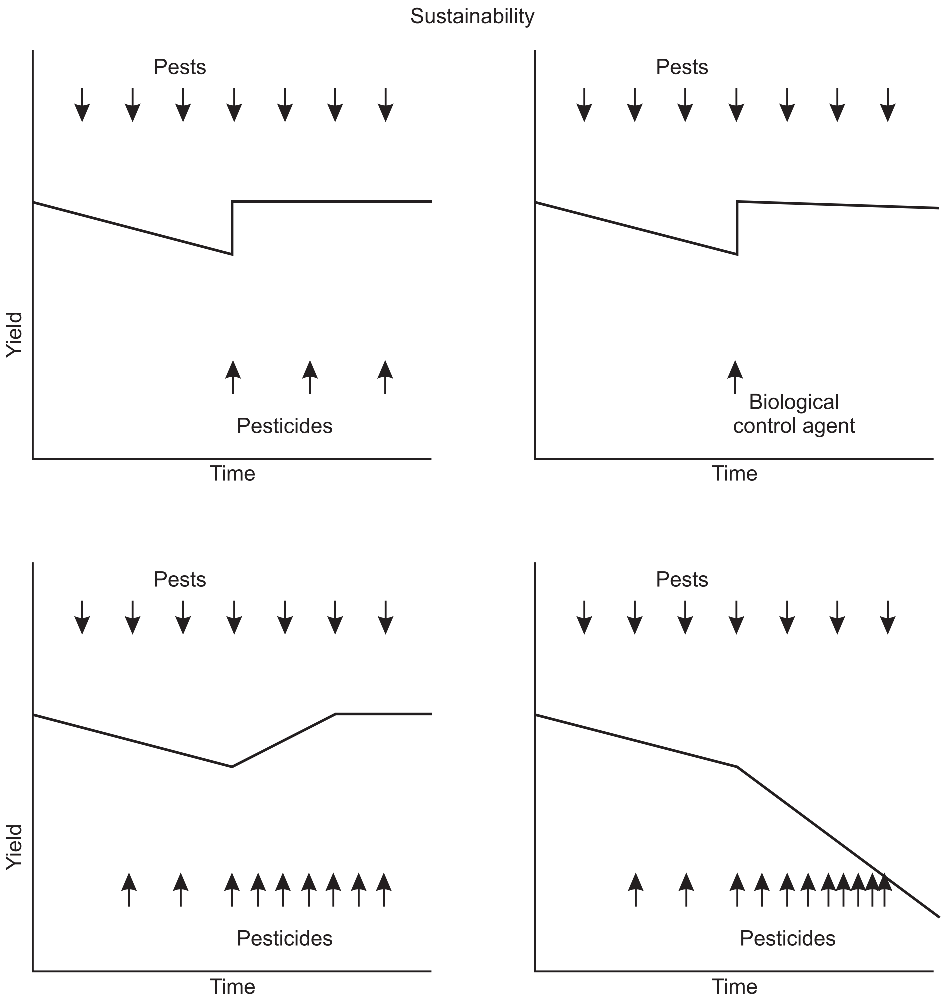

Figure 6.3 *The effect of pest control on sustainability*

Equitability

Equitability is defined as the evenness of distribution of the productivity of the agroecosystem among the human beneficiaries. Once again, the productivity may be measured in many ways, but, commonly, equitability will refer to the distribution of the total production of goods and services of the agroecosystem under consideration, i.e. the field, farm, village or nation. The human beneficiaries may be the farm household, or the members of a village or a national population.

Equitability may be measured by a Lorenz curve, Gini coefficient or some other related index (Lorenz, 1905; Gini, 1912; Kuznets, 1955; Theil, 1967; Atkinson, 1970, 1975; Gastwirth, 1972; Sen, 1973, 1976; Fields, 1980; Kakwani, 1980). In practice, though, it is difficult to define equitability in a purely positive sense, the measures available reflecting different value judgements. Equitability is thus often the evenness of distribution of productivity among the human beneficiaries according to need.

Factors Affecting System Properties

Although the four properties, described above, are the key properties in determining the social value of an agroecosystem there are a large number of other ways that can be used to characterize an agroecosystem. Examples include energy and materials conservation, diversity, autonomy, market penetration and some measure of cultural acceptability. Each of these, however, can be shown to contribute to social value through one or more of the four primary properties, in much the same way as birth rate contributes to the productivity of a population or photosynthesis to the growth of a plant. Thus materials conservation can contribute to productivity but also has a major effect on stability and sustainability; diversity contributes to all four primary properties, although in rather complex ways; and cultural acceptability is an important component of sustainability and equitability.

An early step in the analysis of a given agroecosystem is to identify the important factors and processes that affect the primary system properties. Table 6.2 shows one such list for the high altitude villages in the Karakoram mountains of northern Pakistan, produced during an Agroecosystem Analysis workshop (Conway et al, 1985).

Agricultural Development

The four properties are linked with each other, both within an agroecosystem and between agroecosystems at different levels in the hierarchy. However, the linkages are complex and frequently negative in effect. If we now regard the properties as

Table 6.2 *Key variables and processes affecting the system properties of villages in northern areas of Pakistan (after Conway et al, 1985)*

Positive	*Negative*
Productivity	
Construction of Karakoram Highway	Shortage of cultivable land
Development of new land	Shortage of water
Inorganic fertilizers	Weeds, pests and diseases
New wheat and fruit varieties	Seasonal labour shortage
Introduction of seed potato cultivation	
New credit loan system	
Stability	
Integration of crops and livestock	Crop pests and diseases
Cooperative marketing	Livestock diseases
Improvement of irrigation channels	Temperature fluctuations
Sustainability	
Farmyard manure	Glacier movement
Crop rotation (wheat, potatoes)	Mudflows, avalanches
Training of village livestock specialists	Earthquakes
	River bank erosion
	Virus of seed potatoes
	Overuse of pesticides
Equitability	
Traditional cooperation	Sale of land
Creation of Village Organizations	Education
Rotation of pasturing	Emigrant labour
Development of new land	

normative indicators of performance, rather than neutral descriptors, then agricultural development will involve significant trade-offs between them. For example, a large-scale irrigation project may achieve greater overall productivity yet be at the expense of sustainability and equitability. Similarly, too much emphasis on equitability may inhibit productivity. Within a farm, high stability and sustainability may depend on a complementary diversity of crop fields and livestock systems, each of which produces less than its maximal potential and is more variable in yield and individually less sustainable than is the total farm. A similar situation can occur between the nation and its agricultural regions.

The trade-offs can be seen clearly in the history of agriculture. Each combination of properties can be thought of as an agroecosystem strategy, successive phases of agricultural development reflecting different priorities and hence strategies. The following selected examples from agricultural history are intended to illustrate these points.

The origins of agriculture

Much is known about the where, when, and, to some extent, how, of the origins of agriculture, but there is still considerable controversy over the why (Reed, 1969; Higgs and Jarman, 1972; Bender, 1975; Clark, 1976; Cohen, 1977; Orme, 1977). It is generally accepted that agriculture, by which I mean the cultivation or husbandry of domesticated plants and animals, began independently in at least six widely dispersed regions of the world – the Fertile Crescent (*c.* 9500 BP), Mesoamerica (*c.* 7000 BP), South America (*c.* 6000 BP), South-West China (*c.* 7000 BP) and South-East Asia (*c.* 6000 BP) and Northern India (*c.* 8500 BP). The difficult question to answer is why such a revolutionary event should have occurred in such widely dispersed places, at roughly the same time.

A number of cultural explanations have been proffered (Braidwood and Howe, 1960; Braidwood and Willey, 1962; Ucko and Dimbleby, 1969) as have hypotheses which suggest agriculture was a response to the pressures of an adverse period of climate (Childe, 1936) or of population growth (Cohen, 1977). In each case the writers have assumed, explicitly or implicitly, that the crucial advantage of agriculture over hunting and gathering was its greater productivity. However, a number of arguments suggest that, at least initially, it may have been the relative stability of agriculture that was more important.

Hunter-gathering can be highly productive: the Pacific Coast Indians of North America, for example, were able to support themselves at much higher densities than agricultural groups elsewhere in the continent (Kroeber, 1939; Baumhoff, 1963). But the basic hunter-gatherer foods – migratory salmon, acorns, wild cereals – usually show dramatic year-to-year fluctuations, Moreover, many of the centres of origin exhibit highly seasonal and variable climates and are characterized by mosaics of 'good' and 'bad' food-producing environments. Significantly, the archaeological evidence reveals that, at least in the Fertile Crescent and Mesoamerica, agriculture remained a minor contribution to food supply for long after its inception, 4000 years in the case of Mesoamerica (Flannery, 1969; Bray, 1977). As Boserup (1965) suggests, agriculture may have begun by small daughter bands migrating, in response to local population pressure, into areas more marginal for the wild staple crops. Here the yields were likely to have been even less stable and cultivation and domestication may have arisen as a response to this pronounced instability.

Once, however, agriculture began to spread into other regions of the world, particularly to temperate climates, its superiority in productivity terms was clearly apparent and it was rapidly adopted (Clark, 1965; Ammerman and Cavalli-Sforza, 1971). There were consequences, though, for sustainability and equitability. Early irrigation bought stresses from rising water tables and salinity; grain yields in Sumer dropped from 1850kg/ha to 650kg/ha between 2400 BC and 1700 BC (Jacobsen and Adams, 1958) and there is archaeological evidence of erosion turning arable to wasteland (Dennell and Webley, 1975). Equitability, too, may have declined wherever agriculture became associated with family ownership of land.

Manorial agriculture

One of the longest lasting agroecosystems in history was the manorial system, introduced into Britain by the Anglo-Saxons in the 7th century and persisting until the 14th century (Aston, 1981). Although considerable differences arose from place to place, the essential features of the system remained remarkably constant (Gras, 1925; Ernle, 1961; Stenton, 1965; Baker, 1983). The ecological basis of its sustainability was the three-course rotation of the open fields (two course on poorer land, Gray, 1915), that followed a sequence of winter wheat or rye, spring sown oats, barley, beans or other legumes and then a ploughed fallow. This helped prevent the build up of pests, diseases and weeds, while marling and a limited use of manure ensured a good soil structure. Sustainability was promoted also by the strict control enforced by the village council over cultivation dates, stocking rates and the allocation of land (Ault, 1965).

Despite the hierarchy of the feudal system there appears to have been a relatively high degree of equitability, at least among the landholding peasants. The individual strips in the open fields were allocated so that each family received a fair share of good and bad land while grazing rights on the open fields and on the commons were equally shared.

Productivity, though, was low. Cereal yields were little changed from those of the wild harvests several thousand years before in the Fertile Crescent (Harlan, 1967). Returns to seed were only three- to six-fold. Oats and barley gave the highest yields per acre but the return on the seed sown was lower than that of wheat. A good idea of the stability of production can be obtained from a remarkable set of manorial records (Figure 6.4). Oats were the most stable crop and this may explain why it was the mainstay of the peasant's food. Note that in the very wet years of 1315–1317 wheat yields were greatly reduced while oats were little affected. Pretty (1981) has analysed the responses of these crops to disturbance and shown that oat yields recovered more quickly than wheat following a bad year. Oats were also more stable in terms of price.

Eventually, the manorial system did break down, partly under the pressure of growing population. By the early 14th century productivity was falling, to the extent that some land was being abandoned (Titow, 1969). Other contributing factors were the growth of a monetary economy replacing that based on allegiances and barter, and the pressure for social change. The process was also accelerated by the outbreak of plague, known as the Black Death, which entered Britain in 1348.

The collapse of the manorial system and the enclosure of the open fields to produce individual estates and farms caused great hardship among the peasantry but increased productivity per unit of land and labour. Moreover, it made possible the application of the 18th century scientific revolution. associated with the names of Townshend, Coke, Bakewell, Tull and others, which managed to combine high productivity with sustainability based on rotations incorporating roots and legumes and intensive recycling of crop and livestock waste (Plumb, 1952; Kerridge, 1955; Parker, 1955; Riches, 1967; Chorley, 1981).

Figure 6.4 *Cereal yields for 14 manors under the jurisdiction of the Bishop of Winchester, 1283–1349*

Modern western agriculture

The dominant factor in western agriculture during the latter part of the 20th century has been protectionism. In the UK, for example, the experiences of the great agricultural depressions, notably at the end of the 19th century and in the 1930s, led to the passing of the Agricultural Act of 1947 which introduced a wide range of subsidies and guaranteed prices for most major agricultural products. Subsequently, the creation of the Common Agricultural Policy (CAP) in 1957 under the European Economic Commission (EEC) instituted the right to comparability of income between workers in the agricultural and industrial sectors throughout most western European countries and ensured this through a complicated system of external tariff walls, levies, intervention prices and export refunds. European farmers have been protected from the fluctuations in world markets and productivity has risen dramatically. Over the past three decades nitrogen fertilizer applications in the UK have risen from 200,000 to over 1,400,000 tons, and cereal yields from an average 3 tons/ha to 6 tons/ha while the number of farm workers has declined from 800,000 to under 400,000 (Conway, 1984). Large EEC surpluses, notably of beef, milk, cereals, sugar and wine, have been created.

Over the same period land prices have risen and farmers' incomes in Britain doubled, improving in relation to manual and farm workers, whereas other comparable occupations have declined (Bowers and Cheshire, 1983). Although small and marginal farmers have benefited from the subsidies, the bigger, richer and more specialized farmers have benefited more. For the UK as a whole, the CAP system of price guarantees is effectively borne by the public as consumers, rather than as taxpayers, and hence the impact on income distribution has been regressive.

The increased agricultural productivity has also been at the expense of the amenity, recreation and conservation values of the countryside. There have been recent, large-scale losses of ancient woodlands, chalk grasslands, herb rich meadows, heaths, hedgerows, lakes, fens and mires (Nature Conservancy Council, 1984). Moreover, this has occurred at a time when use of the countryside for walking, angling, camping, horseriding and natural history pursuits involves millions of the public and is rising dramatically (Conway, 1984). Pollution from agriculture is also increasing. Water pollution incidents arising from livestock or silage effluent have doubled since 1979 in the UK (WAA, 1986), while in several parts of the country nitrate levels in drinking water supplies are close to new European limits (Young et al, 1976; Oakes, 1981; Wilkinson and Greene, 1982). In these cases the costs of pollution caused by agriculture are borne by the public rather than by the farming community.

How sustainable is this high level of production remains open to debate. There is some evidence for increased soil erosion (Morgan, 1985a, 1985b) and concern is being expressed over soil quality and the danger of growing pesticide resistance. More important, however, is the cost of subsidizing production at the present levels. Western European governments have already instituted milk quotas and are examining the various consequences of moving towards a lower input/lower output agriculture.

In North America protection generally has been at a somewhat lower level. Indeed, part of the cause of current high levels of bankruptcies among US farmers is lack of protection from fluctuating world prices. Average yields per hectare for cereals are generally lower than in Europe (2 tons/ha is the national average for wheat in the US compared to 6 tons/ha in the UK). Nevertheless, there have been dramatic increases in productivity, particularly in returns to labour, resulting from intensive mechanization and inputs of agrochemicals. But soil erosion is now a major threat and in some regions sustainability is being jeopardized by exhaustion of irrigation water supplies (Crosson and Brubaker, 1982; Larson et al, 1983; Brown and Wolf, 1984; Postel, 1984, 1985; Helms and Flader, 1985).

The Green Revolution in Indonesia

My final example concerns the transformation that has occurred over the last three decades in the agriculture of many of the less developed countries (LDCs). Agricultural scientists tend to dislike the phrase 'Green Revolution' with its journalistic overtones. But the exploitation of the new cereal varieties, bred by the International Agricultural Research Centres, with their high pay-off genetic characteristics of resistance to lodging, insensitivity to photoperiod and early maturation, coupled with the organization and distribution of high pay-off inputs such as fertilizers, water-regulation and pesticides, and targeted on the best favoured agroclimatic regions and the most progressive farmers, has all the hallmarks of a successful technological revolution.

The benefits in terms of productivity have been very great. Over the past two decades food production in Asia has grown overall by 15 per cent per capita and many countries in the region are close to cereal grain self-sufficiency. Indonesia's rice production has grown from under 14 million tons in the late 1960s to over 25 million tons in 1984 and the country now has a small surplus.

This dramatic increase in LDC productivity has been accompanied, however, by numerous problems, ranging from pest and disease outbreaks to loss of communal self-help arrangements (Frankel, 1971; Cleaver, 1972; McNeil, 1972; Nickel, 1973; Collier et al, 1974; Griffin, 1974; Hauri, 1974; Palmer, 1976; Collier, 1977; IRRI, 1979, 1980, 1981; Murdoch, 1980; Pearse, 1980; Hayami, 1981; Maunder and Ohkawa, 1983; KEPAS, 1984). In Indonesia the rice production strategy received a severe setback in the mid-1970s due to recurring and devastating outbreaks of brown planthopper (*Nilaparvata lugens*) (Conway and McCauley, 1983). A switch to a new variety, IR36, was followed by a serious attack of tungro disease, necessitating yet new varietal introductions. Large-scale plantings of uniform crop varieties are intrinsically prone to pest and disease build up, particularly where planting is asynchronous (Loevinsohn, 1984). Sustainability in these circumstances is dependent on the crop breeders always staying one step ahead.

Indonesia's rice strategy has also had dramatic effects on labour use and equitability (Conway and McCauley, 1983). Prior to the introduction of the new rice varieties the harvest was open to all members of the village, the poor and landless being able to retain a fixed proportion of the rice they harvested. But the growing number of landless has made it difficult for farmers to control the harvesting so that now it is carried out by contract groups (Collier et al, 1973). The traditional hand-milling of rice by the women of the village, who received grain in lieu of money payment, has also disappeared, replaced by mechanical hulling (Timmer, 1973). And, despite self-sufficiency, malnutrition persists, even in some of the most agriculturally productive villages.

The final question is whether the national effort is sustainable. Indonesia's oil and gas boom is now over and the budget surpluses which subsidized the agricultural revolution are gone. Inevitably, there will be bad years due to pest and disease outbreaks or poor rainfall. These will place a heavy demand on central resources and agencies who will have to deliver what in the past was the function of communal self-help arrangements and the evolved diversity of traditional agroecosystems.

Agroecosystem Analysis and Development (AAD)

Until recently the various agricultural regions of the world differed from each other in the various weights accorded the agroecosystem properties. In the 1930s, for example, conservation agriculture was being practised in Britain while the Dust Bowl was being created in the midwest of the US. But today agriculture is facing a common worldwide challenge. The pursuit of high productivity in both the developed and less developed countries has brought with it declines in sustainability and equitability that increasingly are being regarded as undesirable. Our present priority is for policy research, practical analytical tools and development packages aimed at increasing agricultural sustainability and rectifying undesirable inequities.

One step in this direction has been the development of Agroecosystem Analysis (Conway, 1985a, 1986). This is a technique of multidisciplinary analysis which may be used at any level in the agroecosystem hierarchy, and generates a set of research and development priorities that explicitly take account of the trade-offs between the system properties. The technique has been used so far to determine research priorities for university and government teams (Gypmantasiri et al, 1980; KKU-Ford, 1982a, 1982b; KEPAS, 1985a, 1985b), development priorities in project design (Limpinuntana and Patanothai, 1984; Conway et al, 1985) and to evaluate project performance and recommend corrective actions (Conway and Sajise, 1986).

A second component of AAD (Conway, 1985b) is the further development and refinement of a variety of packages that promise high productivity without loss of sustainability or equitability. Such packages include Integrated Pest Management, multiple cropping, crop livestock polyculture, agroforestry, communal resource use, communal water control, social forestry and integrated handcraft manufacture.

The next step is to devise ways of incorporating these concepts, tools and packages into formal policy and project design in such a way that the trade-offs are made explicit and accounted for in as rigorous a manner as is currently customary for conventional economic analysis.

Interdependent Social-Ecological Systems and Adaptive Governance for Ecosystem Services

Carl Folke, Johan Colding, Per Olsson and Thomas Hahn

Introduction

The pre-analytic vision of this chapter is that human societies and globally interconnected economies are parts of the dynamics of the biosphere, embedded in its processes and ultimately dependent on the capacity of the environment to sustain societal development with essential ecosystem services and support (Odum, 1989; Millennium Ecosystem Assessment, 2005). Throughout history humans have shaped nature and nature has shaped the development of human society (Turner et al, 1990; Redman, 1999). The human dimension has expanded and intensified and become globally interconnected, through technology, capital markets and systems of governance with decisions in one place influencing people and ecosystems elsewhere (Holling, 1994). Reduced temporal variability of renewable resource flows in some parts of the world has resulted in increased spatial dependence on other areas on earth, reflected in for example widespread ecosystem support to urban areas (Folke et al, 1997). Humanity has become a major force in structuring ecosystem dynamics from local scales to the biosphere as a whole (Steffen et al, 2004).

In this context it becomes clear that patterns of production, consumption and well-being develop not only from economic and social relations within and between regions, but in order to be sustained they also depend on the capacity of ecosystems throughout the world to support societal development (Arrow et al, 1995). Social conditions, health, culture, democracy and matters of security, survival and the environment are interwoven in a grand panorama of regional and worldwide dependency.

Sometimes change is gradual or incremental. During these periods of steady progress, things move forward in roughly continuous and predictable ways. At other times, change is abrupt, disorganizing or turbulent. During such periods, experience is often insufficient for understanding, consequences of actions are ambiguous, and the future of system dynamics often uncertain (Gunderson and Holling, 2002). Evidence points to a situation where periods of abrupt change are likely to increase in frequency and magnitude (Steffen et al, 2004), which poses new fundamental challenges for science, management, policy and governance.

Theories, models and policies for resource and environmental management have to a large extent been developed for gradual or incremental change situations focusing on a unique state with assumptions of linear dynamics and generally disregarding interactions across scales. Recent research has revealed that the implementation of such theory and policy tend to invest in controlling a few selected ecosystem processes, at the expense of key ecological functions, in the urge to fulfil economic or social goals (e.g. Gunderson et al, 1995; Holling and Meffe, 1996; Allison and Hobbs, 2004). This behavioural pattern causes loss of resilience (capacity to buffer change and continue to develop) of desired states (Holling, 1973; Folke, 2006a). Loss of resilience results in vulnerable systems. Historical loss of resilience has put whole regions and cultures into vulnerable states with constrained options for development (Kasperson et al, 1995; Redman, 1999; Schröter et al, 2005). Vulnerable systems subject to change may easily shift from one state (stability domain, basin of attraction) into another (Walker and Meyers, 2004). When such shifts occur the common focus tends to be on the event that revealed the shift and not on the variables, processes and trajectories that caused loss of resilience prior to the event.

To what extent are human societies adapting their capacity for learning and foresight to deal with this new global and challenging situation? We agree with the findings of the Millennium Ecosystem Assessment that the societal capacities to manage the Earth's ecosystems are evolving more slowly than humanity's [over]use of the same systems. Conventional resource models, based on single resources and linear dynamics, are of limited use for the purpose of navigating society towards sustainability.

The perspective presented here emphasizes the following features:

1 society and nature represent truly *interdependent social-ecological systems*;
2 social-ecological systems are *complex adaptive systems*;
3 *cross scale and dynamic interactions* represent new challenges for governance and management in relation to interdependent social-ecological systems and ecosystem services.

Research for sustainability increasingly addresses the intricate feedbacks of social-ecological systems, their complex dynamics and how they play out across spatial and temporal scales. A deeper understanding of coupled systems undergoing change is essential in this context. The implications for current management and policy are challenging.

Here, we provide a brief overview of the three features and then turn to a discussion of systems of adaptive governance (Dietz et al, 2003, Folke et al, 2005) that allow for responding to, adapting to and shaping environmental change. We highlight some features of such governance systems by focusing on management practices of human groups involved with ecosystems and social mechanisms behind such management, including social taboos, social networks, bridging organizations, leadership and actor groups. Societies face the challenge of dealing with unpredictability, uncertainty and change and how to build resilience to periods of abrupt change and allow for transformations into more desirable social-ecological pathways.

The Three Features

Interdependent social-ecological systems

In our view, there are neither natural or pristine systems without people nor social systems without nature (Folke, 2006b). Social and ecological systems are not just linked but truly interconnected and co-evolving across spatial and temporal scales (Berkes and Folke, 1992; Norgaard, 1994). We refer to them as *social-ecological systems* (Berkes and Folke, 1998) emphasizing the humans-in-the-environment perspective (Berkes et al, 2003). It is close to impossible to truly understand ecosystem dynamics and their ability to generate services without accounting for the human dimension. Focusing on the ecological side only, as a basis for decision making for sustainability, simplifies reality so much that the result is distortions and leads to incomplete and narrow conclusions. For example, an observed shift in a lake from a desired to a degraded state may indicate that the lake has lost resilience, but if there is capacity in the social system to respond to change and restore the lake, the social-ecological system is still resilient (Carpenter and Brock, 2004; Bodin and Norberg, 2005).

The same is true for social sustainability. Despite a vast literature on the social dimension of resource and environmental management, studies have predominantly focused on investigating processes within the social domain only, treating the ecosystem largely as a given, an external 'black box', assuming that if the social system performs adaptively or is well organized institutionally, it will also manage resources and ecosystems in a sustainable fashion. A human society may show great ability to cope with change and adapt if analysed only through the social dimension lens (Huitric, 2005). But such an adaptation may be at the expense of changes in the capacity of ecosystems to sustain the adaptation, and may generate traps and breakpoints in social-ecological systems (Allison and Hobbs, 2004).

There has been substantial progress in understanding the social dimension of ecosystem management, including organizational and institutional flexibility for dealing with uncertainty and change (e.g. Lee, 1993; Grumbine, 1994; Westley, 1995; Berkes and Folke, 1998; Danter et al, 2000; Gunderson and Holling, 2002; Berkes et al, 2003; Dietz et al, 2003; Anderies et al, 2004; Armitage, 2005; Ostrom, 2005) and social capital and conflict (e.g. Ostrom and Ahn, 2003; Adger, 2003;

Table 7.1 *Social-ecological practices and mechanisms of local communities and traditional societies in the case studies of the Berkes and Folke (1998)* Linking Social and Ecological Systems *volume*

1 Management practices based on ecological knowledge

- A Practices found in conventional resource management and in local and traditional societies
  - Monitoring resource abundance and change in ecosystems
  - Total protection of certain species
  - Protection of vulnerable life history stages
  - Protection of specific habitats
  - Temporal restrictions of harvest
- B Practices mainly found in local and traditional societies
  - Multiple species management
  - Maintaining ecosystem structure and function
  - Resource rotation
  - Succession management
- C Practices related to the dynamics of complex systems
  - Management of landscape patchiness
  - Watershed-based management
  - Managing ecological processes at multiple scales
  - Responding to and managing pulses and surprises
  - Nurturing sources of ecosystem renewal

2 Social mechanisms behind management practices

- A Generation, accumulation and transmission of local ecological knowledge
  - Reinterpreting signals for learning
  - Revival of local knowledge
  - Folklore and knowledge carriers
  - Integration of knowledge
  - Intergenerational transmission of knowledge
  - Geographical diffusion of knowledge
- B Structure and dynamics of institutions
  - Role of stewards/wise people
  - Cross-scale institutions
  - Community assessments
  - Taboos and regulations
  - Social and religious sanctions
- C Mechanisms for cultural internalization
  - Rituals, ceremonies and other traditions
  - Cultural frameworks for resource management
- D World view and cultural values
  - A world view that provides appropriate environmental ethics
  - Cultural values of respect, sharing, reciprocity and humility

Source: Adapted from Folke et al, 1998a.

Pretty, 2003; Galaz, 2005). Challenges for the social sciences have been raised in this context (e.g. Scoones, 1999; Abel and Stepp, 2003). Social sources of resilience such as social capital (including trust and social networks) and social memory (including experience for dealing with change) (Olick and Robbins, 1998; McIntosh, 2000) are essential for the capacity of social-ecological systems to adapt to and shape change (Folke et al, 2003).

Complex adaptive systems

In our view, social-ecological systems are complex adaptive systems characterized by historical (path) dependency, non-linear (non-convex) dynamics, regime shifts, multiple basins of attraction and limited predictability (Costanza et al, 1993). Theories of complex systems portray systems not as deterministic, predictable and mechanistic, but as process dependent organic and self-organizing with feedbacks between multiple scales (e.g. Kaufmann, 1993; Holland, 1995; Arthur, 1999; Levin, 1999). The ecosystem-based approach recognizes the role of the human dimension in shaping ecosystem processes and dynamics (Dale et al, 2000) and that human actions have pushed ecological systems into less productive or otherwise less desirable states with negative consequences for human livelihood and security. The existence of 'regime shifts' in ecosystems is an area of intense research (Scheffer et al, 2001) with examples from forests, lakes, wetlands, coastal areas, fisheries, coral reefs (Folke et al, 2004), grazing lands (Scholes and Walker, 1993), agriculture (Rockström, 2003) and marine systems (Troell et al, 2005; Grebmeier et al, 2006). In some cases, these shifts may be irreversible or too costly to reverse (Mäler, 2000).

The human dimension reflects properties of complex adaptive systems such as a diverse set of institutions and behaviours, local interactions between actors and selective processes that shape future social structures and dynamics (Holland et al, 1986; Arthur, 1999; Janssen and Jager, 2001; Lansing, 2003). Complexity makes it hard to forecast the future. Not only are forecasts uncertain, the usual statistical approaches will likely underestimate the uncertainties since key drivers like climate and technological change are unpredictable and may change in non-linear fashions (Kinzig et al, 2003; Peterson et al, 2003). Gunderson (2001) nicely illustrates the need for learning and flexibility in the social system when confronted with alternative and uncertain explanations of ecosystem change.

The complex adaptive systems approach shifts the perspective on governance from aiming at controlling change in resource and ecosystems assumed to be stable, to enhancing the capacity of social-ecological systems to learn to live with and shape change and even find ways to transform into more desirable directions following change (van der Leeuw, 2000; Berkes et al, 2003; Norberg and Cumming, 2007).

It is in this context that the *resilience* perspective becomes central. Resilience is the capacity to absorb change, reorganize and continue to develop. The concept of resilience was invented to address the paradox of how change and persistence work together (Holling, 1973). Resilience research addresses how systems assimilate disturbance and make use of change for innovation and development, while simultaneously maintaining characteristic structures and processes (Folke, 2006a). It is argued that managing for resilience enhances the likelihood of sustaining and developing desirable pathways for societal development in changing environments where the future is unpredictable and surprise is likely (Gunderson and Holling, 2002; Adger et al, 2005).

Cross-scale and dynamic interactions

Social-ecological systems are linked across temporal and spatial scales and levels of organization. Human capacities for abstraction and reflexivity, forward-looking action, and technology development are strikingly different from ecological systems (Westley et al, 2002) and enable human systems to transcend constraints of ecological scale. Local groups and communities are subject to decisions from regional levels and connected to global markets and vice versa (Berkes et al, 2006). A social-ecological system can avoid vulnerability at one timescale through the technology it has adopted. Similarly, resilience at one spatial extent can be subsidized from a broader scale, a common pattern in human cultural evolution (Redman, 1999; van der Leeuw, 2000) and exacerbated by technology, capital markets and financial transfers that mask environmental feedback.

Such feedbacks and their cross-scale interactions in relation to resilience are in the focus of a truly integrated social-ecological systems modelling of agents and ecosystem with multiple stable states (e.g. Carpenter et al, 1999; Janssen and Carpenter, 1999; Janssen et al, 2000; Carpenter and Brock, 2004; Bodin and Norberg, 2005). Recent work suggests that complex systems 'stutter' or exhibit increased variance at multiple scales in advance of a regime shift (Carpenter and Brock, 2006). Such increases in variance help characterize regime shifts, and may even allow early warning indicators of some regime shifts. Furthermore, multiple thresholds and regime shifts at different scales and in different and interacting ecological, economic and social domains are proposed to exist within regional social-ecological systems (Kinzig et al, 2006).

New insights are emerging on cross-scale interactions in social-ecological systems (Gunderson and Holling, 2002; Young, 2002; Cash et al, 2006) including dynamics of social and economic drivers of land use change (Lambin et al, 2003) and on governance systems that allow for learning and responding to environmental feedback and change (Dietz et al, 2003). Good ecosystem management requires governance and management approaches that can deal with the change and uncertainty inherent in social-ecological systems and match social and ecological structures and processes operating at different spatial and temporal scales (Folke et al, 1998b; Brown, 2003).

Adaptive Governance for Ecosystem Services

The capacity to adapt to and shape change is an important component of resilience in social-ecological system (Berkes et al, 2003). In a social-ecological system with high adaptability the actors have the capacity to reorganize the system within desired states in response to changing conditions and disturbance events (Walker et al, 2004). This includes social sources of resilience for dealing with uncertainty and change and a focus on adaptive capacity (Folke et al, 2003), learning and innovation in social-ecological systems and even the capacity to transform into improved pathways or trajectories (Folke et al, 2005).

Because of cross-scale interplay, positive feedbacks causing non-linear dynamics and possible shifts between alternate states in interdependent social-ecological systems, new approaches to governance will be required for guiding management and policy of ecosystem services towards sustainability. Based on several case studies Folke et al (2003) identify four critical factors for social-ecological systems that interact across temporal and spatial scales that seem to be required for dealing with ecosystems dynamics during periods of rapid change and reorganization:

1 learning to live with change and uncertainty;
2 combining different types of knowledge for learning;
3 creating opportunity for self-organization toward social-ecological resilience;
4 nurturing sources of resilience for renewal and reorganization.

Governance and management systems have to be designed to incorporate these factors. The emerging perspective of adaptive governance (Dietz et al, 2003; Folke et al, 2005) represents one such approach. Adaptive governance conveys the difficulty of control, the need to proceed in the face of substantial uncertainty, and the importance of dealing with diversity and reconciling conflict among people and groups who differ in values, interests, perspectives, power and the kinds of information they bring to situations (Dietz et al, 2003). Such governance fosters social coordination that enables adaptive co-management of ecosystems. Adaptive co-management combines the dynamic learning characteristic of adaptive management (Gunderson et al, 1995; Carpenter and Gunderson, 2001) with the linkage characteristic of collaborative management (Wollenberg et al, 2000; Gadgil et al, 2000; Ruitenbeek and Cartier, 2001; Folke et al, 2003; Borrini-Feyerabend et al, 2004). For such governance to be effective it requires an understanding of both ecosystems and social-ecological interactions.

Adaptive governance relies on multi-level arrangements, including local, regional, national, transnational and global levels, where authority has been reallocated upward, downward and sideways away from central states. It refers to a type of governance that is dispersed across multiple centres of authority (Hooghe and Marks, 2003), 'pluricentric' rather than 'unicentric' (Kersbergen and Waarden, 2004), and characterized by non-hierarchical methods of control (Ostrom, 1998; Stoker, 1998). The common property resource research refers to such nested, quasi-autonomous decision making units operating at multiple scales as polycentric institutions (Ostrom, 1998; McGinnis, 2000; Dietz et al, 2003).

We have previously proposed that there are, at least, four interacting aspects to be concerned about in adaptive governance of complex social-ecological systems with cross-scale dynamics (Folke et al, 2005).

1 *Building knowledge and understanding of resource and ecosystem dynamics*; detecting and responding to environmental feedback in a fashion that sustains the capacity of the environment to provide ecosystem services requires ecological knowledge and understanding of ecosystem processes and functions (Berkes and Folke, 1998). All sources of understanding need to be mobilized and management of complex adaptive systems may benefit from the combination of different knowledge systems.
2 *Feeding ecological knowledge into adaptive management practices*; successful management is characterized by continuous testing, monitoring, and re-evaluation to enhance adaptive responses acknowledging the inherent uncertainty in complex systems (Carpenter and Gunderson, 2001). It is increasingly proposed that knowledge generation of ecosystem dynamics should be explicitly integrated with adaptive management practices rather than striving for optimization based on past records. This aspect emphasizes a learning environment and knowledge generation with associated institutions (e.g. Brown, 2003). Forming a learning environment that accepts continuous testing and adaptation requires leadership within management organizations (e.g. Danter et al, 2000) and collaboration within social networks (Janssen et al, 2006).
3 *Support flexible institutions and multi-level governance systems*; the adaptive governance framework is operationalized through adaptive co-management where the dynamic learning characteristic of adaptive management is combined with the multi-level linkage characteristic of co-management (Olsson et al, 2004a). The sharing of management power and responsibility may involve multiple often polycentric institutional and organizational linkages among user groups or communities, government agencies, and non-governmental organizations including support from legal, political and financial sources to ecosystem management initiatives.
4 *Deal with external perturbations, uncertainty and surprise;* it is not sufficient for a well functioning multi-level governance system to be in tune with the dynamics of the ecosystems under management. It also needs to develop adaptive capacity for dealing with change in e.g. climate, disease outbreaks, hurricanes, global market demands, subsidies and governmental policies. The challenge for the social-ecological system is to enhance the adaptive capacity to deal with disturbance, to face uncertainty and be prepared for change and surprise. A resilient social-ecological system may even make use of disturbances as opportunities to transform into more desired states. Non-resilient social-ecological systems are vulnerable to external drivers and change.

Management practices for dealing with ecosystem change

Holling (1978) proposed 'Adaptive management' – a constantly changing management system, not only to meet the continuously changing and unpredictable ecosystem, but also to learn from it. Adaptive ecosystem management is an ongoing process, an organized way to deal with uncertainty and learn from management actions (Gunderson et al, 1995). Basically such adaptive management can be divided into:

- A conceptual system model, sometimes expressed as a computer simulation model that represents available knowledge and understanding of the system processes, structure and elements.
- A set of strategies that represents management policies or actions.
- A set of criteria for judging the success of the implementation of management actions and policies.
- A process that continuously evaluates and responds to the effects of management actions on the system and incorporates lessons learned in a new set of strategies to improve management.

Walters (1997) in his review of adaptive management argues that a reason for failure lies in management stakeholders showing deplorable self-interest, seeing adaptive-policy development as a threat to existing research programmes and management regimes, rather than as an opportunity for improvement. This is why it becomes important to address the social dimension and contexts for adaptive governance in relation to ecosystem management such as processes of participation, collective action and learning.

Policy increasingly emphasizes the involvement of local users and land owners in adaptive ecosystem management. Involving local resource users can improve incentives for ecosystem management (Agrawal and Gibson, 1999; Fabricius and Koch, 2004). In addition, traditional and local knowledge about resources and ecosystem dynamics in communities can provide unique information about local conditions and complement scientific knowledge in ecosystem management efforts (e.g. Berkes et al, 2000; Olsson and Folke, 2001; Becker and Ghimire, 2003; Aswani and Hamilton, 2004; Sheil and Lawrence, 2004).

But still few ecological inventories or stakeholder analyses (that tend to focus on conflicting interests) capture human resources in the landscape or the social structures and processes underlying incentives and values for ecosystem management.

Social-ecological inventories and local stewards of ecosystem services

Social-ecological inventories have been suggested to improve ecosystem management (Schultz et al, in press). Such inventories identify people with ecosystem knowledge that practice ecosystem management. Social-ecological inventories help visualize ecosystem management on the ground in relation to ecosystem services, focusing on local steward groups acting outside official management plans. In a social-ecological inventory, conducted in a river basin of southern Sweden, local steward groups, their ecosystem management activities, motives and social networks were identified. Methods included interviews, participatory observations and review of documents and other written material. The inventory revealed a rich diversity of steward groups that manage and monitor a range of ecosystem services at different spatial scales. Contributions of local stewards include on-site ecosystem management, long-term and detailed monitoring of species and ecosystem dynamics, responses to environmental change, generation of local ecological knowledge employed in management practices, public support for ecosystem management and specialized networks (Schultz et al, in press).

Such local stewards of ecosystem services in dynamic landscapes are to be found also in strongly human-dominated environments like urban areas. For example, Colding et al (2006) demonstrate that green spaces such as golf courses, allotment areas and domestic gardens covers more than twice the area of protected lands and are managed by local steward groups below the level of municipalities. These areas play a significant role in urban ecosystem services generation, but they and their stewards are seldom recognized in this capacity in urban planning schemes.

Practices and ecosystem dynamics

Berkes and Folke (1998, 2002) identified management practices of local groups that make ecological sense and where people have developed practices to deal with ecosystem dynamics including abrupt periods of change. Traditional practices for ecosystem management include multiple species management, resource rotation, ecological monitoring, succession management, landscape patchiness management, and practices of responding to and managing pulses and ecological surprises. There exist practices that seem to reduce social-ecological crises in the events of large-scale natural disturbance such as creating small-scale ecosystem renewal cycles, spreading risks and nurturing sources of ecosystem reorganization and renewal (Colding et al, 2003; Folke et al, 2003).
